Thermally stimulated current analysis (TSCA) is another member of the TEA group of techniques. In TSCA, the sample is subjected to a constant electric field and the current that flows through the sample is measured as a function of temperature. The mode of operation usually involves heating the sample to a high temperature under the applied field followed by quenching to a low temperature. This process aligns dipoles within the sample. The polarization field is then switched off and the sample is reheated and the current flow resulting from the relaxation of the induced dipoles back to the disordered state is monitored.

TSCA finds applications in the pharmaceutical industry in which the stability of lyophilized products is a critical issue. Freeze-drying a drug formulation is commonly used to preserve the active component during storage. The active ingredient is diluted and embedded in an excipient formulation during the freeze-drying process. The physical properties of the excipient in the solid phase determine the overall stability of the formulation. Knowledge of the glass transition and melting temperatures of the formulation are essential to the prediction of product shelf-life. Also, the interaction of the product with water is essential to modeling the freeze-drying process. It is generally recognized that melting transitions are best determined by DSC. However, glass transitions are usually associated with very small energy changes and hence are often difficult to detect unambiguously by DSC. A feature of TSCA is that the current flow is directly proportional to the strength of the applied electric field. Thus, it is possible to magnify weak transitions simply by increasing the polarization voltage.

Dielectric analysis measures changes in properties of a sample as a function of temperature as it is

subjected to a periodic applied electric field. Changes in the dielectric constant of a material with temperature can arise from changes in molecular motion as a result of phase transitions or chemical transformations. For example, dielectric analysis of copper sulfate pentahydrate shows stepwise changes of dielectric constant in unison with stepwise dehydration – the latter being revealed by TG. Dielectric analysis is particularly useful for studying order–disorder crystal transitions and the diffusion dynamics of lattice-bound water molecules in inorganic salts.

## Miscellaneous ‘Less-Common’ TA Techniques

A form of EGA involves heating the sample at a constant rate in the probe of a mass spectrometer and the resulting TA technique is known as ‘programmed probe analysis’ or more simply as ‘analytical pyrolysis’. By such a process, samples are pyrolyzed in high vacuum since the sample environment is equivalent to the operating pressure of the mass spectrometer. This technique has been used by Bratspies *et al.* to determine thermal decomposition mechanisms of metal complexes, particularly tin dithiocarbamate complexes and this definitive study has been reviewed.

Mandelis has reviewed ‘photothermal’ TA techniques. Thermal waves may be optically induced in solid samples by modulated irradiation. These thermal waves then interact directly with the sample and such interaction is detected by suitable sensors. Acoustic waves may be simultaneously induced and detected. These techniques have specialized application to solid-state systems to determine thermal transport properties such as thermal conductivity, diffusivity/effusivity, and specific heat capacity. These techniques are of particular significance in the determination of mechanisms of solid-state phase transitions.

Parkes *et al.* have described a new technique – ‘microwave thermal analysis’, which, as the name implies, involves heating the sample by microwave radiation. This heating method has a major advantage over the conventional method using a programmed furnace, in that the microwave radiation heats by direct molecular interaction rather than by conduction or convection and thus temperature gradients in the sample are markedly decreased. The uniformity and rapidity of heating of samples enhances the resolution of thermal events. MWTA is related to the thermoelectrometry techniques in that it depends on changes of dielectric properties of the sample. With suitable refinements, MWTA has a promising future.

## TA Developments (1996–2005): A Summary Overview

Traditionally, the full range of ‘classical’ TA techniques has been associated with three major problems: the ‘relatively’ long experimental measurement times; the small (mass) size of samples; and the ‘averaged nature’ of the data output. A fourth drawback of this group of techniques is that, in general, no single technique is able to provide sufficient information to characterize the thermal behavior of a material. It is these drawbacks that have perhaps limited the development and application range of these techniques. However, these EAS reviews have revealed that these limitations have been essentially overcome, not only by the introduction of new TA techniques and further development of the less common ones, but also by refinement of the well-known traditional TA techniques. ‘Long experimental times’ have been very significantly reduced in modern DSC systems, such that DSC has become the definitive method for measurement of heat capacity in the solid state. New systems such as ‘Hi-Res’ TG<sup>TM</sup> have significantly reduced experimental time but not at the expense of resolution and sensitivity. The new SCTA techniques can be associated with long experimental times, but ‘time-resolved SCTA’ appears to have addressed this problem. ‘Preparative-scale’ TG systems are now in evidence, which provide sensitivity levels comparable to the wide range of small-scale TG systems. The problem relating to the ‘averaged nature of data output’ has been comprehensively overcome by the development of ‘modulated’ TA techniques and perhaps this has been the most significant recent advance in TA technology. Overcoming the principal disadvantages of TA techniques, coupled with the development of new, powerful, specialized techniques such as  $\mu$ -TA and DETA, have ensured a prominent future for TA in the twenty-first century – particularly in terms of TA being the preeminent analytical group of techniques in materials science.

### Introduction

In conventional absorption spectrometry, the light intensity absorbed by a sample is given by the Lambert–Beer law:

$$\log(I_0/I) = A \quad [1]$$

where

$$A = \epsilon bc \quad [2]$$

$I_0$  and  $I$  are the light intensities before and after passage through the sample, and  $A$  is the absorbance. The parameter  $\epsilon$  is the molar absorptivity,  $b$  is the pathlength, and  $c$  is the sample concentration. When the sample is diluted and the absorbance is sufficiently small, eqn [1] can be rewritten as

$$(I_0 - I)/I = 2.303A \quad [3]$$

In order to measure low light absorption, it is necessary to stabilize the intensity of the light introduced into the sample and to reduce fluctuations of the

transmitted light. Such fluctuations are caused by variation of the beam path due to refractive index changes that occur when there is turbulent flow in the sample. Thus, the sensitivity of conventional absorption spectrometry is independent of the light intensity and cannot be improved even when a laser with a large output power is used as a light source.

In 1964, Gordon and co-workers observed the build-up and decay of a transient optical phenomenon when a sample cell was placed in the resonator of a helium–neon laser. This phenomenon is produced by a thermal lens effect induced by low light absorption in the sample. Local heating and the resulting refractive index gradients generated in the sample cause it to act as a diverging lens. Since the magnitude of this effect is proportional to the intensity of the light, it is possible to measure low levels of light absorption by increasing the output power of the laser. This spectroscopic technique has been used for measuring low levels of light absorption caused by overtone vibrations of the molecule in the visible region and for measuring fluorescence quantum yields of dyes.

### Principles

### Introduction

In conventional absorption spectrometry, the light intensity absorbed by a sample is given by the Lambert–Beer law:

$$\log(I_0/I) = A \quad [1]$$

where

$$A = \epsilon bc \quad [2]$$

$I_0$  and  $I$  are the light intensities before and after passage through the sample, and  $A$  is the absorbance. The parameter  $\epsilon$  is the molar absorptivity,  $b$  is the pathlength, and  $c$  is the sample concentration. When the sample is diluted and the absorbance is sufficiently small, eqn [1] can be rewritten as

$$(I_0 - I)/I = 2.303A \quad [3]$$

In order to measure low light absorption, it is necessary to stabilize the intensity of the light introduced into the sample and to reduce fluctuations of the

transmitted light. Such fluctuations are caused by variation of the beam path due to refractive index changes that occur when there is turbulent flow in the sample. Thus, the sensitivity of conventional absorption spectrometry is independent of the light intensity and cannot be improved even when a laser with a large output power is used as a light source.

In 1964, Gordon and co-workers observed the build-up and decay of a transient optical phenomenon when a sample cell was placed in the resonator of a helium–neon laser. This phenomenon is produced by a thermal lens effect induced by low light absorption in the sample. Local heating and the resulting refractive index gradients generated in the sample cause it to act as a diverging lens. Since the magnitude of this effect is proportional to the intensity of the light, it is possible to measure low levels of light absorption by increasing the output power of the laser. This spectroscopic technique has been used for measuring low levels of light absorption caused by overtone vibrations of the molecule in the visible region and for measuring fluorescence quantum yields of dyes.

### Principles

A schematic diagram of a thermal lens spectrometer is shown in **Figure 1**. The laser beam is focused by a lens and is directed at the sample. When the sample is placed at the focal point of the lens, a strong thermal

**Figure 1** Schematic diagram for a thermal lens spectrometer.

lens effect takes place. However, the lens effect cannot be measured using the laser beam since it is formed at the focal point of the laser. The sample is then shifted slightly from the focal point and the beam expansion caused by the thermal lens effect is measured. This is accomplished quantitatively by placing a pinhole in front of a photodetector, which then measures the change in light intensity at the beam center. Typical waveforms are shown in **Figure 2**.

A model has been proposed to describe the thermal lens effect in which the signal intensity is expressed by

$$[I_{be}(t=0) - I_{be}(t=\infty)]/I_{be}(t=\infty) = 1 - \theta + \theta^2/2 \quad [4]$$

$$\theta = P_{abs}(dn/dT)/\lambda k \quad [5]$$

where  $I_{be}(t=0)$  and  $I_{be}(t=\infty)$  are the light intensities at the beam center at  $t=0$  and  $r=\infty$ , respectively. The parameter  $\theta$  is a dimensionless quantity and is approximately the difference between the thermally induced phase shifts at  $r=0$  and  $r=\omega$ , where  $r$  is the distance from the beam center and  $\omega$  is the beam radius. The value of  $P_{abs}$  is the power absorbed by the sample,  $(dn/dT)$  is the variation of refractive index with temperature,  $\lambda$  is the wavelength of the laser, and  $k$  is the heat conductivity. The higher-order term,  $\theta^2/2$ , can be neglected when the thermal lens is optically thin and the signal intensity is sufficiently small (e.g.,  $<0.1$ ). In this case,  $P_{abs}$  is expressed by

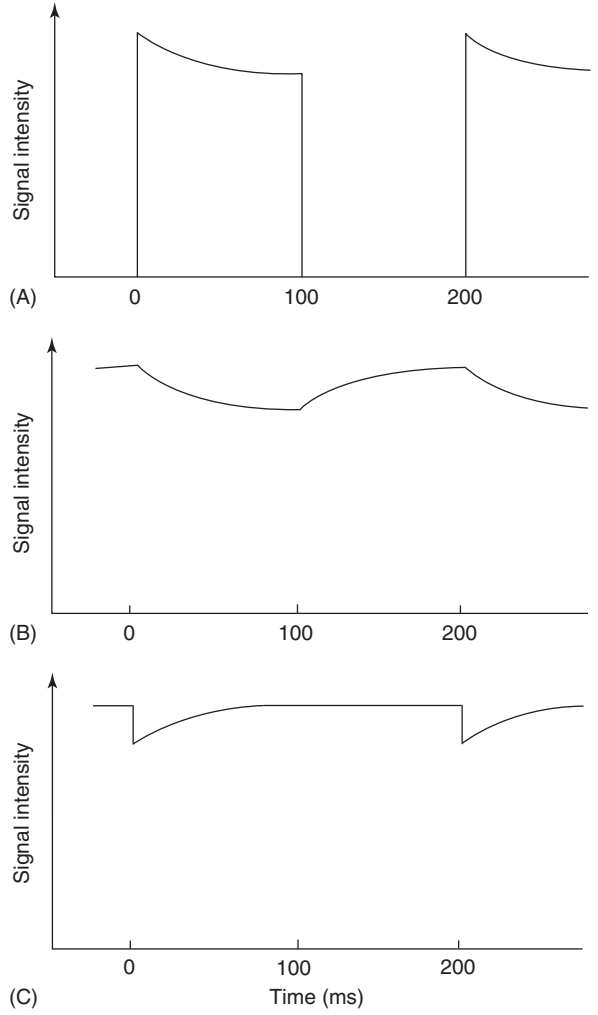

$$P_{abs} = 2.303PA \quad [6]$$

where  $P$  is the power of the laser beam introduced. Equation [4] then becomes modified to:

$$[I_{be}(t=0) - I_{be}(t=\infty)]/I_{be}(t=\infty) = 2.303E_cA \quad [7]$$

$$E_c = P(dn/dT)/\lambda k \quad [8]$$

where  $E_c$  is the enhancement factor, i.e., the sensitivity of thermal lens spectrometry relative to conventional absorption spectrometry, obtained under continuous-wave (CW) excitation.

**Figure 2** Transient curve of thermal lens signal: (A) single-beam system using CW laser; (B) dual-beam system using CW exciting laser; (C) dual-beam system using pulsed exciting laser.

When a pulsed laser is used as an exciting source, a different model is used. Under one-photon excitation, the signal intensity is expressed by

$$[I_{be}(t=\infty) - I_{be}(t=0)]/I_{be}(t=0) = 2.303E_1A \quad [9]$$

$$E_p = -3^{3/2}(E_l/\lambda_p\omega_{0p}^2)(1/\rho C_p)(dn/dT) \quad [10]$$

where  $E_p$  is the enhancement factor obtained under pulsed laser excitation,  $E_l$  is the pulse energy of the exciting laser,  $\lambda_p$  is the wavelength,  $\omega_{0p}$  is the beam waist radius,  $\rho$  is the density of the sample, and  $C_p$  is its specific heat capacity.

The enhancement factor is proportional to the output power of the exciting laser under CW laser excitation and to the pulse energy under pulsed laser excitation. Accordingly, the sensitivity of thermal

lens spectrometry is improved by using an intense laser source. In CW thermal lens spectrometry, the enhancement factor is not affected by the laser beam radius, so that the sensitivity is independent of the focusing condition. This is due to the more rapid heat dissipation across the beam radius that occurs when the laser beam is more tightly focused. In pulsed thermal lens spectrometry, the enhancement factor is inversely proportional to the square of the beam radius. Thus, the sensitivity can be substantially improved by concentrating the beam tightly, although this reduces its effective pathlength.

When the exciting beam is interrupted, the signal decays by thermal diffusion across the heating region. The transient decay curve is given by

$$I_{\text{be}}(t)/I_{\text{be}}(t=0) = [1 - \theta(1 + t_d/2t)^{-1}]^{-1} \quad [11]$$

(model of eqn [4])

or

$$I_{\text{be}}(t)/I_{\text{be}}(t=0) = (1 + 2t/f_d)^{-2} \quad (\text{model of eqn [9]}) \quad [12]$$

$$t_d = \omega^2/4D \quad [13]$$

$$D = k/\rho C_D \quad [14]$$

where  $t_d$  is the decay time constant,  $\omega$  is the beam radius at the sample, and  $D$  is the thermal diffusivity. Therefore, the decay time depends on the beam radius in CW thermal lens spectrometry as well as in pulsed thermal lens spectrometry.

In later work the observed signal was found to be lower than the theoretical value due to the aberrant nature of the thermal lens. In this case, the experimental value becomes consistent with the theoretical value when it is multiplied by a factor of 0.52.

## Enhancement Factor

The sensitivity of thermal lens spectrometry is estimated simply by calculating the enhancement factor. The values in **Table 1** are obtained by assuming that an argon ion laser producing 1 W or a dye laser (500 nm,  $\omega = 0.1$  mm) producing 1 mJ is used as a typical exciting source. The enhancement factor of the medium is not determined by the solute or sample gas but is primarily determined by the solvent or buffer gas.

These calculated values provide a guideline for the application of thermal lens spectrometry to trace analysis. An enhancement factor of 140 is obtained under CW laser excitation even in the worst case, that of water. Thermal lens spectrometry is therefore

**Table 1** Enhancement factors obtained under CW ( $E_c$ ) and pulsed ( $E_p$ ) laser excitation

Medium	$E_c$ (1 W)	$E_D$ (1 mJ)
<i>Liquid</i>		
Water	140	20
Ethanol	2400	210
Benzene	4700	430
Carbon tetrachloride	5900	440
<i>Gas</i>		
Helium	0.8	140
Air	35	770
Carbon dioxide	87	950
Benzene	535	1700

Values multiplied by 0.52 (see text).

useful for sensitive detection of the sample. Moreover, organic solvents give enhancement factors 20–40 times greater than that of water. This is due to organic solvents having heat conductivities about four times smaller than that of water, while the variation of refractive index with temperature is about six times larger for organic solvents than for water. This result indicates that extraction of the sample to be analyzed from an aqueous solution into an organic solvent is advantageous in terms of improved sensitivity. However, the enhancement factor is rather small for gas-phase samples in CW thermal lens spectrometry; this is due to the rapid dissipation of heat in gaseous samples. On the other hand, the enhancement factor is relatively large for gas-phase samples in pulsed thermal lens spectrometry, although the values for liquid-phase samples are much lower than those in CW thermal lens spectrometry.

These differences originate in the thermo-optical properties of the different media and in the nature of CW or pulsed laser excitation. For example, the decay time is generally longer for a liquid-phase sample, since it has a higher density. Heat generated locally within the sample builds up sufficiently in CW thermal lens spectrometry. In gas-phase samples heat is dissipated more rapidly, producing a weaker thermal lens. Furthermore, the background signal due to light absorption by impurities and overtone vibrations in the solvent can be effectively subtracted when a CW laser with a stable output power is used. Therefore, CW thermal lens spectrometry is the preferred technique for application to liquid-phase samples.

In contrast, pulsed laser excitation forms a thermal lens instantly and this lens effect is detected before heat dissipation in the sample medium occurs. The density of a gas-phase sample is low, which decreases the heat capacity per unit volume and increases the

temperature rise. Thus, a strong thermal lens occurs in gas-phase samples in pulsed thermal lens spectrometry. The enhancement factor can be further improved by tightly focusing the beam for a gas-phase sample. In liquid-phase samples laser breakdown occurs, limiting the maximum pulse energy that can be used. Pulsed thermal lens spectrometry is therefore preferable for gas-phase sample applications.

### Improvement of Enhancement Factor

In order to improve the enhancement factor, several approaches have been developed and their advantages have been verified experimentally. When the temperature of a binary liquid mixture of aniline and cyclohexane is adjusted to be slightly below the critical temperature ( $T_c = 30.585^\circ\text{C}$ ), the signal intensity is enhanced 44 times over that for the individual solvents. This anomalous phenomenon is considered to be due to a thermally induced concentration gradient. A similar effect is observed for the supercritical fluid carbon dioxide. The value of  $(dn/dT)$  is greatly increased at around the supercritical point ( $T_c = 31.0^\circ\text{C}$ ,  $P_c = 72.8\text{ atm}$ ), providing an enhancement factor 150 times larger than for carbon tetrachloride. The apparent enhancement factor increases when an exothermic (or endothermic) chemical reaction occurs during irradiation by the exciting laser. Local heating induces a strong temperature gradient, and therefore an anomalous thermal lens effect is (apparently) observed. The effects described above provide an extremely large enhancement factor, although an increasing fluctuation of the background signal also occurs. It is necessary, therefore, to carefully control experimental parameters such as temperature, pressure, and mechanical stability of the optical table.

### Exciting Laser

The enhancement factor calculated theoretically is obtained experimentally only when an ideal laser source is used. The enhancement factor is strongly affected by the beam quality of the laser. Thus, a laser with a single transverse mode must be used to obtain an enhancement factor close to the theoretical one. A CW laser, such as an argon ion laser, is usually operated in the single mode and is preferred in thermal lensing spectrometry. A pulsed laser, such as a dye laser pumped by an excimer laser, provides rather poor beam quality, unless the beam shape is specially controlled by using a pinhole followed by amplification. The enhancement factor obtained experimentally in pulsed thermal lens spectrometry is usually small in comparison with the theoretical value. Aberration of the focusing lens may also affect the

enhancement factor and should be minimized by careful selection of the lens.

### Sample

The enhancement factor is strongly affected by the sample position, as shown in Figure 3. Thermal focusing and defocusing effects are observed when the sample is positioned before and after the focal point, respectively. In theoretical calculations of the enhancement factor, the sample is assumed to be positioned at a point a distance of  $\sqrt{3}$  times the confocal distance after the focal point to provide a maximum signal. The confocal distance is defined as the distance between the focal point and the position at which the beam radius is  $\sqrt{2}$  times that at the beam waist. Thus, in order to achieve the optimum enhancement factor the sample should be carefully positioned and be sufficiently thin. Particles suspended in the sample introduce severe scatter into the laser light, since the laser beam is tightly focused in the sample. The sample must therefore be filtered carefully before making the measurement. Temperature variation of the sample may also affect the sensitivity, but most experiments are carried out without temperature control since it is only the temperature gradient that occurs in a short time period that is measured in thermal lens spectrometry.

### Measurement

In order to measure the thermal lens signal, the light intensities at  $t = 0$  and  $t = \infty$  must be measured. The

**Figure 3** Dependence on cell position of enhancement factor.

transient signal is recorded by a waveform digitizer and is analyzed by a microcomputer. The observed signal is fitted to a theoretical curve, and  $I(t=0)$  and  $I(t=\infty)$  are calculated. Using this technique, a minimum absorptivity of  $7.8 \times 10^{-8}$  is detected using a 160 mW argon ion laser. By placing reference and sample cells before and after the focal point, the background drift due to variation of the laser output power is cancelled out. In most experiments a pinhole is placed in front of the photodetector to allow measurement of the light intensity at the beam center. However, the noise can be reduced by measuring a one-dimensional beam profile with an image sensor. The precision, i.e., the sensitivity, is improved 3.8 times by using this technique. Further improvement is achieved by replacing the pinhole with an optical mask, consisting of  $3 \times 10^4$  pixels, and its density is proportional to a parabolic function, i.e.,  $F(r) = r^2/r_{\max}^2$ . This technique allows two-dimensional reduction of noise without using a digital computation technique. The precision in signal measurement is improved by a factor of 16. Other spectrometric techniques have been developed to improve the enhancement factor, e.g., by using a Mach-Zehnder interferometer or an intracavity quenching effect.

### Single-Beam and Dual-Beam Configurations

A thermal lens spectrometer is easily constructed using a single laser. However, a waveform digitizer equipped with a microcomputer must be used to analyze the transient curve, as described above. On the other hand, it is possible to use two lasers, i.e., an exciting laser and a probe laser, in thermal lens spectrometry. These laser beams, emitting at different wavelengths, are coaxially aligned and focused into a sample cell. The exciting beam is modulated by a beam chopper to form a periodic thermal lens and is interrupted by a filter placed in front of a pinhole. The signal can then be measured easily by using a lock-in amplifier, cf. **Figure 2B**. However, the beam diameter, i.e., the beam divergence, of the probe laser is usually different from that of the exciting laser. This means that the two laser beams are not focused at the same position. Mode mismatch also occurs due to aberration of the focusing lens – the focal length of the lens depends on the wavelength of the light and is therefore different for the exciting and probe lasers. Mode mismatch results in asymmetry in the dependence on the sample position; the maximum enhancement factor obtained by the thermal focusing effect is different from that obtained by the thermal defocusing effect. It is also possible to conduct a dual-beam experiment using a single laser. In this technique, the laser beam

is split into two parts by a polarization beam splitter. One part is used as the heating beam and the other part as the probe beam.

## Applications

### Gas Phase

**Figure 4** shows a thermal lens spectrum for ammonia recorded by using a dye laser pumped by an excimer laser as an exciting source. The laser wavelength is extended to the near-infrared (IR) region by stimulation due to Raman effect. This spectrum consists of the third overtone vibration of the  $\nu_1$  band for ammonia. A similar spectrum is recorded for atmospheric nitrogen dioxide. The detection limit is  $4 \text{ ng ml}^{-1}$ , which is three orders of magnitude better than that of a conventional absorption spectrometer. The enhancement factor achieved is 16 at a pulse energy of 1.3 mJ, which is lower than the theoretical value by a factor of 33. As pointed out earlier, this is due to the poor beam quality of the dye laser used. Nitrogen dioxide is also measured by using a 700 mW argon ion laser. The linear analytical range extends to  $250 \mu\text{g ml}^{-1}$ , the detection limit being  $5 \text{ ng ml}^{-1}$ . The enhancement factor observed is 7. This small enhancement factor is ascribed to the application of CW thermal lens spectrometry to a gas-phase sample. However, the detection limits achieved in the above experiments are substantially better than detection limits obtained by conventional absorption spectrometry. This is due to efficient reduction of noise by periodic modulation of the exciting beam using boxcar or lock-in amplifiers. A thermal lens spectrum is also measured in the IR region by using a CW line-tunable carbon dioxide laser (7 W), in which differentiation of several organic gases is

**Figure 4** Thermal lens spectrum (TLS) for ammonia.

demonstrated. The detection limit reported is 12 ppb for methanol, which corresponds to an absorbance of  $2.7 \times 10^{-7}$ . Use of a pulsed carbon dioxide laser (100 mJ) increases the enhancement factor for a gas-phase sample. The detection limit reported is  $10 \text{ ng ml}^{-1}$  for dichlorodifluoromethane.

### Liquid Phase

In one analytical application of thermal lensing spectrometry, Cu(II) is determined after color development with ethylenediaminetetraacetic acid using a 4 mW helium–neon laser. The enhancement factor achieved is 2.0, and the minimum detectable absorbance is  $1.0 \times 10^{-3}$  corresponding to 3.3 ng of copper. More sensitive analysis is achieved by using an argon ion laser with a larger output power (600 mW). For example, Fe(II) is determined by chelation with bathophenanthroline disulfonic acid in an aqueous solution. The enhancement factor achieved is 72, with a reported detection limit of  $5 \times 10^{-10} \text{ mol l}^{-1}$  ( $0.03 \text{ ng ml}^{-1}$ ). For an Fe(II)–bathophenanthroline disulfonate complex extracted into chloroform, the detection limit is further improved to  $3 \times 10^{-11} \text{ mol l}^{-1}$ . The enhancement factor is 1040, the minimum detectable absorbance being  $6 \times 10^{-7}$ . By using a CW dye laser pumped by an argon ion laser, phosphorus is determined to  $5 \text{ pg ml}^{-1}$  based on the molybdenum blue method. Phosphorus is also measured by solvent extraction of a molybdophosphate/auramine ion pair into 1:2 isobutanol/hexane. The compound has an absorption band at 440 nm, and a helium–cadmium laser emitting at 442 nm (100 mW) is used for sample excitation. The detection limit reported is  $600 \text{ pg ml}^{-1}$ , which is restricted by variable blank measurement. A water-soluble analyte such as  $\text{Tb}^{3+}$  is measured by dissolving it in a reverse micelle, instead of using solvent extraction.

A pulsed dye laser is also used for measurement of liquid-phase samples, because of its wide tunability. For example, Cu(II) is determined by using Pb(II)-tetrakis (4-*N*-methylpyridyl)porphinetetra-*p*-toluene sulfonate; a sharp Soret band appears at 422 nm ( $\epsilon = 1.5 \times 10^5 \text{ l mol}^{-1} \text{ cm}^{-1}$ ). However, this approach is less successful because of a poor background subtraction capability, which is ascribed to pulse-to-pulse instability of the pulse energy of the pulsed dye laser.

### Practical Thermal Lens Systems

In order to simplify the thermal lens spectrometer, a compact and inexpensive diode laser may be used as an exciting source. For example, phosphorus forms a blue complex with molybdenum, which has an

absorption band in the near-IR region (780–870 nm). Phosphorus is determined in an aqueous solution to 2.2 and  $0.7 \text{ ng ml}^{-1}$  with single- and dual-beam systems, respectively. When the sample is measured after solvent extraction into 2-butanol, the detection limits are improved to  $0.21 \text{ ng ml}^{-1}$  for both methods. The maximum enhancement factor achieved is 61 with a 10 mW laser. The minimum detectability is limited primarily by blank absorption occurring from the solvent. The solvent blank can be reduced by using chloroform, but the detection limit obtained by ion pair extraction of the complex into chloroform using myristyldimethylbenzylammonium chloride (Zephiramine) is unchanged since in this case the minimum detectability is limited by reagent blank.

A similar procedure is followed in the determination of Fe(II) with 2-nitroso-5-diethylaminophenol using ion pair extraction into chloroform. The enhancement factor achieved experimentally is 47. The detection limit for Fe(II) is  $8 \times 10^{-9} \text{ mol l}^{-1}$ , which is three to four times better than that obtained by conventional absorption spectrometry. The detection limit is governed by the background signal originating from the impurity of Fe(II) contained in the reagent.

In the thermal lens system, many optical components are necessary, including a beam splitter, a focusing lens, a sample cell, and a pinhole. The positions of these components must be carefully optimized and be fixed rigidly throughout the experiment. This requirement raises difficulties in the application of thermal lens spectrometry to practical analysis. A simple thermal lens system can be constructed using a pair of optical fibers placed facing each other, as shown in Figure 5. In this system the sample is placed between the fibers; in other words the fibers are immersed in the sample. This configuration removes the sample cell and allows detection of the sample in a high-pressure vessel or a high-temperature reactor. When the laser beam is emitted from the optical fiber, it diverges as if focused at the distal end of the fiber. In order to retain the high

Figure 5 Fiber-coupled thermal lens spectrometer.

beam quality of the laser, a single-mode fiber must be used for light introduction; many transverse modes appear in multimode fibers and therefore the focusing capability is degraded. It should be noted that the single-mode fiber is designed for a specific wavelength and the fiber should be matched to the laser wavelength used. A multimode fiber may be used for light collection. The enhancement factor achieved is 42, but this enhancement factor is only 5% of the theoretical value. This is attributed to the small core diameter (6  $\mu\text{m}$ ) of the fiber, resulting in a short confocal distance (31  $\mu\text{m}$ ). This distance is much shorter than the pathlength (1 cm) assumed in calculating the enhancement factor. In order to extend the effective pathlength, an optical fiber with a larger core diameter would seem to be necessary, but such fibers are not yet commercially available.

### Gas Chromatography Detector

Samples such as dichlorodifluoromethane, chlorotri-fluoromethane, and ethanol are separated by a conventional gas chromatograph column (Carbowax 20M) and are excited at the P32 line of the carbon dioxide laser (933  $\text{cm}^{-1}$ ). The reported detection limit is an absorbance of  $2.5 \times 10^{-7}$ .

### Liquid Chromatography Detector

In early work, nitroaniline isomers were separated by a conventional octadecyl silane (ODS) column and detected by a thermal lens spectrometer consisting of a 190 mW argon ion laser. The detector volume was 10  $\mu\text{l}$ , and the sample pathlength 1 cm. The enhancement factor achieved was 120 and the time constant was 28 ms. The detection limits were from the sub-nanogram to several-nanograms range. In more recent work, the minimum absorbance detected has been improved to  $1.2 \times 10^{-6}$ . Thermal lens spectrometry has also been applied to microcolumn liquid chromatography. The detection volume and the pathlength are 0.5  $\mu\text{l}$  and 1 mm, respectively. The minimum absorbance detected is  $2\text{--}4 \times 10^{-6}$ . When an open tubular column is used for sample separation, the pathlength is further reduced to 100 or 200  $\mu\text{m}$ . The reported baseline drift is approximately  $3 \times 10^{-5}$  absorbance. The detection limit achieved is 30 pg for *o*-nitroaniline. In order to reduce the detection volume further, cross-beam thermal lens spectrometry (thermal refraction spectrometry) is used. Detection limits reported for dimethylaminoazobenzenesulphonyl derivatives are 0.75 fmol, at which only 50 analyte molecules are expected within the probe volume (0.2 pl) at the peak maximum.

### Detector for Electrophoresis

Many biological samples are now separated by polyacrylamide gel electrophoresis. For example, protein is separated on a gel plate and is stained by Coomassie Brilliant Blue R250 or G250. This is placed on a translator, which is electrically driven for recording a chromatogram. Capillary electrophoresis has recently become popular because of its better sample separation and the capability of real-time sample monitoring. Twenty phenylthiohydantoin-amino acids are separated in a capillary (50  $\mu\text{m}$  ID, 50 cm long), and the sample is detected by a cross-beam thermal lens spectrometer using a highly repetitive krypton fluoride excimer laser with a low pulse energy. The detection limit is  $9 \times 10^{-7} \text{ mol l}^{-1}$  of sample injected in a 0.6 nl volume, corresponding to 0.5 fmol (100 fg) of labeled amino acids.

### Limitations

Thermal lens spectrometry is a sensitive analytical technique for measuring small amounts of light absorption. However, lasers with large output power or large pulse energy are necessary in order to obtain a sufficiently large enhancement factor for an aqueous-phase sample. Thus, small lasers such as an air-cooled argon ion laser or a pulsed dye laser pumped by a nitrogen laser are not suitable for trace analysis. To overcome this problem, the sample may be extracted into an organic solvent to improve the enhancement factor. However, the extraction efficiency is sometimes limited at low sample concentrations. Furthermore, background absorption originating from impurities in the solvent is not negligible, usually occurring in the UV region. At the same time, background absorption originating from overtone vibration of solvent molecules is unavoidable in the near-IR region. Thus, it is necessary to subtract the background signal carefully and effectively.

The absorption band is rather broad, especially for a liquid-phase sample, and at present only CW line-tunable lasers are usable in practice. Spectral selectivity is therefore quite limited in thermal lens spectrometry. Analytical selectivity is improved by a chemical reaction before the measurement, e.g., by chelation of ions with a specific ligand. However, chelation is not necessarily completed at ultratrace levels.

In order to obtain an enhancement factor close to the theoretical one, the sample pathlength must be much shorter than the confocal distance. It is possible to increase the pathlength, e.g., to 10 cm, by focusing the laser beam loosely, but this decreases the time constant in signal decay. To compensate, the

modulation frequency must be decreased, resulting in a poor signal-to-noise ratio in signal detection.

It appears that thermal lens spectrometry is truly advantageous only when it is applied to a chromatograph detector, when a small pathlength is required, e.g., 1 mm or less. In the case of liquid chromatography, the background signal is effectively subtracted by using a stable CW laser. Note that there is no appreciable background signal in gas chromatography using an ultrapure carrier gas. In such chromatography, additional selectivity is given by a separation procedure. However, laser fluorometry is generally more sensitive, and therefore to make the best use of thermal lens spectrometry its application should be restricted to nonfluorescent samples. Many biological samples, e.g., deoxyribonucleic acid, have absorption bands in the visible or UV region, and they are nonfluorescent at room temperature. Moreover, most chelates containing heavy metals are known to be nonfluorescent. Therefore, thermal lens spectrometry may be useful for the measurement of such biological and chemical species. Finally, it is emphasized that the background

originating from the reagent, solvent, and, sometimes, the sample species itself included as an impurity in the reagent must be carefully reduced for ultratrace analysis using thermal lens spectrometry, as it is in other ultrasensitive spectrometric techniques.

## Introduction

This article serves as an overview covering definition, historical development, basic principles, and advantages

of thin-layer chromatography (TLC) in comparison to column chromatography. It concludes with a summary of common applications. Details on theory, instrumentation, plate technology, and method development are covered in subsequent articles.

## Definition and General Description

TLC is a form of liquid chromatography. It is used for rapid separation of samples into components based on differences in their retention behavior. The

stationary phase, usually an adsorbent such as silica gel, is coated onto a rectangular support such as a glass, aluminum, or plastic plate as a thin layer.

Liquid samples are applied as spots or bands onto the dry stationary phase forming a line close to one edge of the plate. The TLC plate is placed vertically in a chromatographic chamber with lid, containing an amount of the liquid mobile phase sufficient to cover the bottom of the chamber, but not reaching up to the application position of samples on the plate (Figure 1). The mobile phase is drawn through the layer by capillary action starting separation when reaching the applied samples (start position). When the front of the mobile phase has moved to a certain predefined height (developing distance) the plate is removed from the chamber, appropriately dried, and, if necessary, derivatized for detection of samples. The resulting chromatogram is evaluated qualitatively by visual or densitometric comparison of the migration distance of the separated components to those of reference standards analyzed simultaneously on the same plate. Often, the behavior of substances during

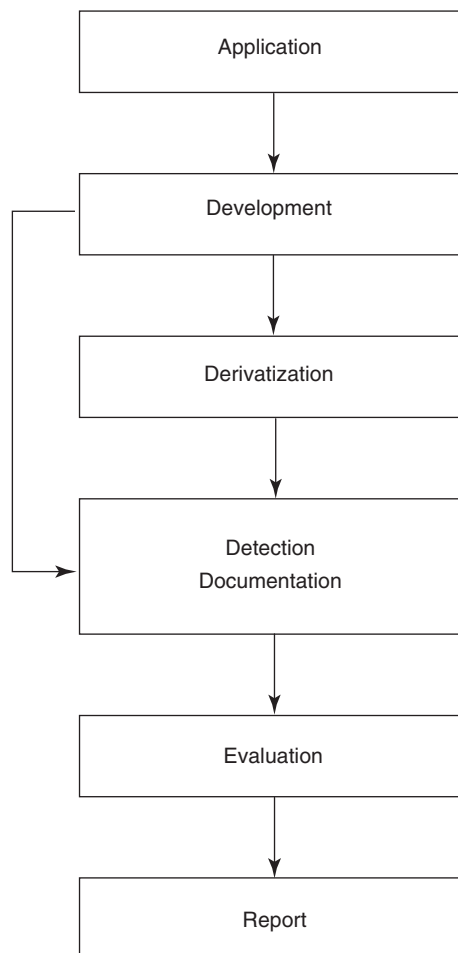

derivatization is also observed. Quantitative determination is possible by comparison of the intensity of the separated zones to those of known standard concentrations.

TLC is a very popular chromatographic technique because it is experimentally simple, enormously flexible, and inexpensive. It can lead rapidly to reliable qualitative and quantitative results primarily based on visual impression.

TLC is an offline technique (Figure 2). An analysis is performed as a sequence of individual steps, which are independent with respect to time and location. Compared to chromatography in columns, which is an online process, this design does not only offer great flexibility for technical solutions but also almost unlimited possibilities for combination of parameters to optimize the chromatographic result. In TLC, a large number of samples can be analyzed and compared to one another simultaneously on the same plate. The actual chromatographic separation provides exactly the same conditions for samples and references and there is no danger of permanently

**Figure 1** Schematic description of the development of a TLC plate.  $Z_0$  is the distance between the application position and the level of the developing solvent. After the mobile phase has reached the desired distance, the plate is removed from the tank.

**Figure 2** Steps of TLC as an offline technique.

contaminating the system by components of the sample's matrix because each plate is used only once. After separation, the TLC plate functions as a storage device for the chromatogram and thus enables multiple detection/evaluation. For all steps of the TLC process modern instruments are on the market, ensuring reproducible results at various levels of sophistication. As an open system the TLC plate is easily affected by environmental factors such as humidity, fumes, light, and mechanical stress during handling. To ensure reproducibility of results this must be taken into account when designing and performing a TLC experiment.

## Historical Development

At the end of the 1930s, adsorption chromatography in columns as introduced by Tswett had become a powerful separation technique for plant extracts and natural products. Simultaneously, the need for a more rapid alternative suitable for identification of separated substances led to the invention of an open chromatographic system. In 1938, Izmailov and Shraiber reported the separation of belladonna alkaloids on a thin adsorbent layer, coated onto microscopic slides. Development of circular chromatograms was achieved by placing small amounts of various solvents to the center of samples previously applied as spots onto the layer. This method was an extremely rapid microtechnique requiring only small amounts of stationary and mobile phases.

In 1944, Consden, Gordon, and Martin took a different approach using the principle of partitioning. This resulted in the invention of paper chromatography, which soon became a universal chromatographic technique. TLC did not advance much further until the 1950s when several significant improvements were made. Kirchner, Miller, and Keller in 1951 incorporated a fluorescent indicator into the stationary phase. Silica gel was becoming the most widely used adsorbent. In 1956, Stahl introduced the term 'thin-layer chromatography'. This, together with Merck developing standardized aluminum oxide, kieselguhr, and silica gel based on Stahl's specifications and Desaga bringing a basic instrument kit to the market, manifested the birth of TLC as a recognized and broadly accepted analytical technique. In 1962, Stahl with his fundamental book, *Thin Layer Chromatography – A Laboratory Handbook*, gave a forum to the leading researchers in the field of TLC and summarized the knowledge of that time. As a standard analytical technique, TLC was soon widely adopted by pharmacopoeias and official method collections. The improvement of

plate materials, culminating in precoated high-performance layers of reproducible quality in the late 1970s, the rapid development of the theoretical foundation, and the appearance of powerful densitometers became the basis for reliable quantitative analyses by TLC. At that time, high-performance liquid chromatography (HPLC) evolved and began to compete with TLC as a quantitative technique. The 1980s saw remarkable improvements particularly in instrumentation, automation of individual TLC steps, and theoretical concepts contributed by Snyder, Kaiser, Ebel, and Geiss. In 1987, Geiss published *Fundamentals of Thin Layer Chromatography*, which is regarded as one of the most influential books on the subject. The *Journal of Planar Chromatography* was founded in 1988 as a platform for discussion of all aspects of modern TLC.

Aside from the traditional way of performing TLC, several other approaches have also been taken. They include forced-flow techniques using centrifugal force, a pump (over-pressured layer chromatography, OPLC), or an electrical field to move the mobile phase. Hyphenated techniques were introduced combining TLC separation with infrared, Raman, or mass spectrometric detection. A technique for analysis of analytes that can be evaporated (IATRO-SCAN) utilizes separation performed on the surface of reusable thin chromatographic rods combined with a flame ionization detector. Also, gradient techniques have been developed for TLC, the most powerful of which is AMD – automatic multiple development – patented by Burger.

Today, TLC is a mature technique that meets all requirements of a modern analytical tool. Although it has lost its dominant role as a routine procedure to HPLC due to the lack of full automation, it is still indispensable for rapid qualitative analyses (identification), as a screening tool, and as a complementary technique in research and development.

## Basic Concepts

### Principles of Separation

The stationary phase in TLC is usually an adsorbent (Table 1) composed of very fine and highly porous particles coated as a thin layer onto a support. Today, the most widely used stationary phase is silica gel 60. With a solvent or solvent mixture as mobile phase, a liquid–solid chromatographic system is formed. Separation of sample components can be primarily described as adsorption chromatography. Sample molecules are retained due to specific interaction on the surface of the stationary phase while

**Table 1** Important inorganic and organic adsorbents

<i>Inorganic</i>	<i>Organic</i>	<i>Bonded phases on silica gel</i>
Silica gel	Cellulose	Octadecyl-, octyl-, dimethyl-, dipenylsilanized
Alumina	Polyamide	Aminopropylsilanized
Kieselguhr (diatomaceous earth)	Sephadex	Cyanopropylsilanized
Magnesium silicate		Diol (propanediol)

migration takes place when the molecules are dissolved in the mobile phase.

A dynamic adsorption equilibrium is established for each sample component. The equilibrium is characterized by a partition coefficient  $K_A$  representing the ratio of concentration of the sample component A in the stationary phase ( $c_s$ ) and in the mobile phase ( $c_m$ );  $K_A = c_s/c_m$ . Separation of two samples A and B can only be achieved if their partition coefficients are different. Typical forces causing adsorption of molecules on the stationary phase include nonspecific dispersion forces, dipole–dipole interactions, acid–base interactions, hydrogen bonding, electrostatic interaction between ions, and others. There are two extreme cases. If the sample is strongly adsorbed and only sparingly soluble in the mobile phase it will remain at the application position. Weakly adsorbed and readily soluble samples will migrate with or close to the solvent front.

A suitable combination of stationary and mobile phase will result in a separation of sample components. They will be located at different migration positions when the development of the TLC plate is interrupted as soon as the mobile phase has reached the specified developing distance. The ability of a solvent to displace an adsorbed sample molecule from the surface of a given stationary phase is called solvent strength. It can be measured as energy that is released when a solvent molecule is adsorbed. Although it is not simply a measure of dipole moment, solvent strength in adsorption chromatography is often expressed as solvent polarity. Adjusting the solvent strength of the mobile phase affects the position of the sample components in the chromatogram. The quality of separation, expressed as resolution between zones of the chromatogram, depends on the selectivity of the TLC system. Adjusting the composition of the mobile phase is the primary way of changing selectivity.

Apart from adsorption phenomena, a variety of other separation mechanisms can be utilized. If chemically bonded phases or liquid stationary phases on an inert support are used as stationary phase, separation is predominantly based on partition

**Figure 3** Schematic presentation of result in TLC. MD, migration distance;  $Z_f$ , distance between application and front;  $R_F = MD/Z_f$ .

equilibria. Examples include octadecyl, aminopropyl, diol, cyanopropyl modified silica gel, impregnated silica gel, and cellulose or kieselguhr. Separations based on ion exchange, complex formation, size exclusion, and even chiral recognition are also performed.

### Describing the Result

In column chromatography, the chromatographic system has a fixed length. Each sample component can be characterized by the time it requires to pass through the column and reach the detector. This is the retention time  $t_R$  and it is measured at the peak maximum. In TLC, the analysis takes a fixed time (development time) during which sample components can migrate. Depending on its retention each sample component will reach a specific migration distance (MD) and remains there as a zone (spot) for detection when the TLC plate is dried (**Figure 3**). A compound with high MD would in comparison have a short retention time in column chromatography, provided the separation mechanism is the same. The MD of a zone is measured in millimeters from the application position to the point of highest

concentration (intensity). When the chromatogram is evaluated densitometrically this point represents the peak maximum. As retention time is dependent on the mobile phase velocity, the migration distance is dependent on the position of the mobile phase front  $z_f$ . Therefore, a relative measure has been introduced. The  $R_F$  value (retardation factor) of a zone is the ratio of its migration distance to that of the mobile phase front.  $R_F = MD/z_f$ .

$R_F$  values are always  $< 1$ . For convenience it is common to multiply the  $R_F$  value by 100 and report  $bR_F$  with two digits. It is possible to compare the migration distance of an unknown (A) to that of a reference compound (ref) to yield the  $R_{rel}$  value.  $R_{rel} = MD_A/MD_{ref}$ .

Although the  $R_F$  value is characteristic for a substance in a given TLC system, it must be treated with caution because it is affected by several parameters. In practice, it is often difficult to reproduce  $R_F$  values exactly. The  $R_{rel}$  value has no physical meaning.

The principle of qualitative analysis is a comparison of  $R_F$  values obtained from samples and standards on the same TLC plate. If two substances are the same they will have the same  $R_F$ . However, different substances may also migrate to the same position. For further confirmation of identity a specific derivatization or recording of the ultraviolet (UV) spectrum of the substances on the plate can be utilized. The size and intensity of the zone of the analyte is visually compared for estimation of quantity to that of standards at several known levels on the same plate. A precise quantitation is possible by scanning or video densitometry by which the absorption or fluorescence of separated zones of each chromatogram track is recorded. The resulting analog curves are integrated and evaluated based on peak height or area. The fundamental requirements for reliable quantitation are baseline resolved zones and symmetric peaks for the compounds in question. The resolution between two zones or peaks can be calculated from the chromatogram (Figure 4).

### Influence of the Developing Chamber

In TLC, the chromatographic system consists of a plate coated with the stationary phase and a developing chamber containing the mobile phase. As seen in Figure 5, a gas phase consisting of components of evaporated solvent molecules is also present. It is a matter of time, geometry, and whether fitting the chamber with filter paper enlarges the surface of the developing solvent, but as long as the chamber is tightly closed, saturation is eventually established.

This means that the vapor in the gas phase is in equilibrium (1) with the developing solvent on the

**Figure 4** The resolution ( $R_s$ ) between two separated peaks is calculated from the chromatogram:  $R_s = 2\Delta Z / W_{B1} + W_{B2}$ .

**Figure 5** The composition of the gas phase is affected by: (1) equilibrium of gas phase with developing solvent on the bottom of the chamber (saturation); (2) and (3) equilibrium between gas phase and stationary phase ((2) absorption of gaseous molecules, (3) evaporation of mobile phase).

bottom of the chamber. When the dry TLC plate is placed in the chamber solvent vapor is readily adsorbed onto the stationary phase. If the stationary phase has no contact with the developing solvent, as it is possible in a twin trough chamber, over time another equilibrium, (2) between the gas phase and the stationary phase is established. This is called preconditioning. It leads to adsorptive saturation of the stationary phase. When the mobile phase rises up the stationary phase a third equilibrium (3) is approached. While (1) is dependent on the vapor pressure of the solvent components and (2) is controlled by adsorptive forces, (3) is affected by both parameters.

During chromatography all three equilibria are effectively influencing each other as well as the chromatographic result. Experimental details, type, and geometry of the chamber are therefore important parameters that can be used to optimize separation. Even in so-called saturated chambers chromatography is typically performed in nonequilibrium, which makes it difficult to mathematically describe all processes in exact detail. Generally, there are neither good nor bad chambers; however, results obtained in one may be quite different from those obtained in another chamber. In consequence, it is imperative for obtaining reproducible results that the chamber and all of its parameters are clearly defined and kept constant. As a rule of thumb saturated chambers tend to give lower  $R_F$  values for the same separation than unsaturated chambers. The zones in saturated chambers are somewhat more diffuse, but reproducibility of the result is much higher than in unsaturated chambers. TLC can also be performed in sandwich chambers, where covering the stationary phase with a counterplate limits the gas phase. As a result of this the stationary phase remains active and cannot be preloaded with solvent molecules. The mobile phase is then separated into its components. So-called secondary fronts are formed and can interfere with the separation. In saturated chambers secondary fronts are usually eliminated because the polar components of the mobile phase are preferably preadsorbed through the gas phase. Secondary fronts are one of the principal drawbacks of OPLC where the gas phase is completely eliminated.

## Practical Approaches

### Sample Application

During sample application two principal requirements must be met. The samples must be precisely and correctly positioned in order to identify separated components based on their migration distance/ $R_F$

**Table 2** Typical parameters for sample application on HPTLC plates

Parameter	Band	Spot
Distance from lower edge of plate in mm	8	10
Minimum distance from left and right edge of plate in mm	10	10
Minimum space in mm between bands/spots <sup>a</sup> in mm	2	2
Band length in mm	8	
Maximum diameter of application spot in mm		4

<sup>a</sup>Most instruments do not allow programming of distance between bands/spots. Therefore distance between tracks (center to center) and band length must be chosen in order to meet the minimum distance requirement. For spot application, volume and application speed have to be determined empirically.

values and the sample volume must be controlled in order to allow quantitative evaluation of the chromatogram. The size of the plate determines the number of samples. Samples should not be applied too close to the edges of the plate and must be evenly and sufficiently spaced for best results. Typical application parameters for high-performance thin-layer chromatography (HPTLC) plates are summarized in **Table 2**. Application of samples can be performed manually or with the help of instruments. For manual application the positions are carefully marked on the TLC plate with soft pencil. Use of a spotting guide helps avoiding any damage to the layer. Samples are transferred with the help of disposable capillaries, graduated micropipettes, or microliter syringes and deposited onto the plate as spots. If larger volumes are applied this is done in portions with intermediate drying of the application position. The smaller the applied spot, the better is the obtainable resolution of the chromatogram. Best results in sample application are obtained with instruments, particularly those that use the spray-on technique. For maximum resolution and best precision in quantitative TLC, samples are sprayed on as narrow bands. Following sample application it is common to mark the desired developing distance on one edge of the plate.

### Chromatogram Development

Chromatogram development is performed in a chromatographic chamber, often called a tank. There are many different kinds of chambers, but flat bottom or twin trough chambers with a rectangular base are most common. The size of the chamber should be appropriate for the size of the plate. A saturated chamber is created, when one or more walls of the chamber are fitted with filter paper, which is thoroughly wetted with the developing solvent. For saturation to establish, the charged chamber is left

closed for a defined period of time prior to introducing the TLC plate and starting development. Unsaturated chambers do not contain filter paper. Chromatography is started immediately after the chamber is charged with developing solvent. The level of solvent in the chamber is chosen in a way that the sample application position on the plate is clearly above it. Most plates are developed in a saturated chamber in vertical position, but horizontal developing chambers are also available (**Figure 6**). With special chambers circular and anticircular development can also be performed. For circular development samples are applied to a square plate around the center forming a circle. The mobile phase is applied to the center of the plate. Anticircular development requires delivery of mobile phase from a ring gap to the plate onto which samples have been applied forming a circle of large diameter.

All developments discussed so far were single developments. Multiple developments are also possible. After intermediate drying of the plate a subsequent development can be performed (1) over the same, (2) over a longer, and (3) over a shorter developing distance. While in case (1) the goal is to improve separation by using the same mobile phase for development, in case (2) the first development over a few millimeters with a strong mobile phase is typically used to concentrate the sample into a narrow application zone. The second development with a suitable mobile phase is used for separation. In case (3), a nonpolar matrix can be removed from the sample and transported to the upper edge of the plate with a weak mobile phase leaving the compounds of interest at the application position. In the second development with a stronger mobile phase the actual separation of the sample is performed.

**Figure 6** Comparison of flat-bottom chamber (A), twin trough chamber (B), and horizontal developing chamber (C): (1) HPTLC plate, (2) glass plate for sandwich configuration, (3) reservoir for developing solvent, (4) glass strip, (5) cover plate, (6) conditioning tray. Examples: The flat-bottom chamber is lined with filter paper soaked with the developing solvent for saturation. Twin trough chambers can be filled with two different liquids and are less solvent-consuming. Horizontal developing chambers are easy to use in sandwich configuration.

When the mobile phase has reached the desired developing distance of typically 6 cm on HPTLC plates and 12 cm on TLC plates development is interrupted, the plate is removed from the chamber, and dried.

### Visualization and Derivatization

One of the most striking features of TLC is the possibility of presenting the chromatographic result visually. Visual detection is possible when the separated sample components are colored, have native fluorescence, or absorb UV light so that they quench the fluorescence of the indicator, which can be built into the layer of the TLC plate. Derivatization can enhance visualization dramatically by improving the detectability of all or selected zones of the chromatogram. Numerous chemical reactions are known to convert the analyte into a colored or fluorescing derivative. Nonspecific reactions such as charring with acid are broadly applicable, whereas specific derivatization such as the reaction of amines with ninhydrin can be used to single out compounds of certain functionality from a separated mixture. The convenient availability of biochemical reactions and *in situ* biological tests add extra flexibility to the detection step in TLC. Examples include inhibition of an enzyme such as choline esterase or measurement of effects on the growth of bacteria or yeast cells.

For chemical derivatization, the developed TLC plate is either sprayed with or immersed into a solution of the reagent. While spraying requires small amounts of reagent and provides great flexibility the advantage of immersion lies in ensuring a homogeneous and reproducible coverage. In many cases derivatization is completed with a heating step using either an oven or a plate heater.

### Densitometric Evaluation

If a separated substance absorbs UV or white light or can be excited to fluoresce, densitometric evaluation of the chromatogram is possible without derivatization. With a densitometer, also called scanner, the tracks of the TLC plate are evaluated by registering the reflected/emitted light when a narrow beam of light of a single wavelength is moved across the plate. A photomultiplier converts the light into an electrical signal, which as a function of migration distance presents the analog curve of the chromatogram. Following integration of the raw data the peak height and/or area can be quantitated. Densitometry is a very sensitive measurement. Typically less than 100 ng of substance per zone can be detected. In some cases, such as aflatoxins, detection limits are in the picogram range. Most modern densitometers allow recording of *in situ* UV spectra, which can be

used to confirm identity or purity of separated compounds.

Densitometry is performed after derivatization, if that improves the detectability of the analyte. Examples include introduction of fluorophoric groups, charring of nonabsorbing compounds, specific color reactions.

### Documentation

Documentation of a TLC chromatogram as an image is conveniently possible. Traditionally photographs have been taken but the availability of electronic devices such as flatbed scanners or digital cameras have simplified the process. The principal advantage of electronic images is their durability. Added benefit is the possibility of qualitative and quantitative densitometric evaluation.

## Special and Hyphenated Techniques

### High-Performance Thin-Layer Chromatography

HPTLC is based on the use of special layers made from narrowly distributed fine particles of  $\sim 5\text{ }\mu\text{m}$ . It is actually not a special technique because all fundamental parameters, theoretical considerations, and practical aspects of classical TLC still apply. However, due to the consequent use of specialized instrumentation HPTLC does not only achieve miniaturization of the chromatogram, but also and more importantly a significant improvement of sensitivity, reproducibility, and separation power. A modern HPTLC workstation including devices for each individual chromatographic step is software controlled and provides good manufacturing or good laboratory practice compliant results similar to that of HPLC and GC instruments.

### Automated Multiple Development

Automated multiple development (AMD) is a gradient technique consisting of a variable number of developments with intermediate drying steps, which are achieved by application of vacuum to the special developing chamber. In a computer-controlled method, each subsequent development proceeds to a higher developing distance using increments of 2–3 mm than the previous step. Furthermore, each run uses a weaker (in adsorption chromatography less polar) mobile phase. As a consequence, the separated zones are repeatedly focused. In combination with the mobile phase gradient this results in a significant increase of the separation power. Results obtained with AMD are predictable and very reproducible.

## Forced-Flow Techniques

The separation efficiency of TLC is limited due to the fact that capillary forces move the mobile phase. Forced-flow techniques are an attempt to solve this problem. One approach, rotational planar chromatography, utilizes centrifugal forces and has become a widely used preparative technique. A circular plate is mounted on a centrifuge and the sample followed by the mobile phase is applied close to the center of the plate. Separated sample components can be collected when they elute from the rotating plate.

Another very flexible forced-flow technique is OPLC introduced by Tyihak and Mincsovcics. The plate is completely sealed on all four edges. Following sample application the plate is covered with a Teflon foil, which is part of a cassette. In a special pressure chamber the cover foil seals the plate in vertical direction under external pressure. With the help of a programmable pump the mobile phase is forced with constant velocity through an inlet in the coversheet of the cassette to travel in a laminar flow through the chromatographic layer toward an outlet located at the opposite edge of the plate. The two principal drawbacks of the technique, which can considerably interfere with the separation and must therefore be minimized in the experimental setup, are solvent demixing resulting in secondary fronts when multicomponent mobile phases are employed and a so-called front of total wetness. This is a disturbance at the region where gas bubbles, which are trapped in the pores of the adsorbent when the mobile phase first enters the layer, are finally displaced by solvent molecules. OPLC has found various analytical, semi-preparative, and preparative applications. The system can be operated in an online mode like HPLC, offline mode like regular TLC, or in a mixed mode.

## Hyphenated Techniques

Several so-called hyphenated techniques have been developed, where the developed TLC plate is transferred to a modified spectrometer to record *in situ* the Fourier transform infrared, surface enhanced Raman, or mass spectra of the separated zones. This way more detailed structural information can be obtained to complement the data from densitometric evaluation. A true hyphenation is the direct application of the eluate from a microbore HPLC column onto an HPTLC plate, which is then developed by AMD.

## Applications

Typical applications of TLC are listed in Table 3. In many areas including herbal, pharmaceutical, and

**Table 3** Major applications of TLC

Sample type	Application
Pharmaceutical	Impurities in synthetic drugs
	Stability tests of synthetic drugs
	Content uniformity
	Pharmacokinetic studies and drug monitoring
	Assay
Industrial	Enantiomeric purity
	Product uniformity
	Impurity determination
	Surfactants, dyes
Herbal	Cleaning validation
	Identity, purity, and stability tests of plant drugs
	Quantitation of marker compounds
Biomedical	Organic acids, lipids
	Carbohydrates
	Porphyryns and bile pigments
	Amino acids, peptides
	Steroids, doping
Nutritional	Mycotoxins (incl. aflatoxins)
	Drug and pesticide residues
	Antioxidants, preservatives
	Pigments, dyes, spices, flavors, vitamins
Environmental	Pesticides residues
	Water and soil analysis
Forensic	Poisons
	Drugs of abuse
	Inks

environmental analyses the flexibility of the technique as a research tool is a great asset. Other applications such as content uniformity, residue, and doping test as well as cleaning validation take advantage of short analysis times due to parallel chromatography of many samples. Qualitatively, TLC is primarily used in general research and in quality control of raw materials for rapid and cost-efficient identification. Quantitative applications include assays, determination of impurities and process monitoring.

### Introduction

Thin-layer chromatography (TLC) as we know it today became established in the 1950s with the introduction of standardized materials and procedures that led to improved separation performance, reproducibility, and a rapid growth in applications. During the 1970s, fine-particle layers and associated instrumentation required for their correct use were introduced. Methods that employed advanced instrumentation for separations became known as high-performance thin-layer chromatography (HPTLC), instrumental TLC, or modern TLC to distinguish it from its parent, now generally referred to as conventional TLC, or simply TLC. Both approaches coexist today because of their complementary

features (Table 1). Conventional TLC provides a quick, inexpensive, and portable method for qualitative analysis. It requires minimal and readily available instrumentation and uses easily learned laboratory skills. HPTLC, on the other hand, uses fine-particle layers for faster and more efficient separations and requires sophisticated instruments for automated sample application, development, and detection. HPTLC affords accurate and precise results based on *in situ* measurements and a record of the separation in the form of a chromatogram (see Figure 1). While there are no barriers to the use of conventional TLC in any analytical laboratory, only those laboratories that have invested in the necessary instrumentation have the option of using HPTLC methods.

TLC is a type of liquid chromatography in which the stationary phase is in the form of a uniform thin layer immobilized on a flat surface rather than packed into a tube (column). In the basic experiment, the sample is applied to the layer as a spot or band near to the bottom edge of the layer. Separations are performed in a closed chamber by contacting the bottom edge of the layer with the mobile phase, in a process referred to as development. In traditional methods, the mobile phase advances through the layer by capillary forces. Alternatively, in forced flow and electrochromatography the mobile phase is driven through the layer by a pressure gradient, centrifugal force, or electroosmosis. In all cases, separation results from the different rates of migration of the sample components in the direction traveled by the mobile phase. After development and evaporation of the mobile phase, the sample components are immobilized in the layer and their position and quantity determined by visual evaluation or densitometry.

### Introduction

Thin-layer chromatography (TLC) as we know it today became established in the 1950s with the introduction of standardized materials and procedures that led to improved separation performance, reproducibility, and a rapid growth in applications. During the 1970s, fine-particle layers and associated instrumentation required for their correct use were introduced. Methods that employed advanced instrumentation for separations became known as high-performance thin-layer chromatography (HPTLC), instrumental TLC, or modern TLC to distinguish it from its parent, now generally referred to as conventional TLC, or simply TLC. Both approaches coexist today because of their complementary

features (Table 1). Conventional TLC provides a quick, inexpensive, and portable method for qualitative analysis. It requires minimal and readily available instrumentation and uses easily learned laboratory skills. HPTLC, on the other hand, uses fine-particle layers for faster and more efficient separations and requires sophisticated instruments for automated sample application, development, and detection. HPTLC affords accurate and precise results based on *in situ* measurements and a record of the separation in the form of a chromatogram (see Figure 1). While there are no barriers to the use of conventional TLC in any analytical laboratory, only those laboratories that have invested in the necessary instrumentation have the option of using HPTLC methods.

TLC is a type of liquid chromatography in which the stationary phase is in the form of a uniform thin layer immobilized on a flat surface rather than packed into a tube (column). In the basic experiment, the sample is applied to the layer as a spot or band near to the bottom edge of the layer. Separations are performed in a closed chamber by contacting the bottom edge of the layer with the mobile phase, in a process referred to as development. In traditional methods, the mobile phase advances through the layer by capillary forces. Alternatively, in forced flow and electrochromatography the mobile phase is driven through the layer by a pressure gradient, centrifugal force, or electroosmosis. In all cases, separation results from the different rates of migration of the sample components in the direction traveled by the mobile phase. After development and evaporation of the mobile phase, the sample components are immobilized in the layer and their position and quantity determined by visual evaluation or densitometry.

### Flow through Porous Layers

TLC is a simple experimental method based on a complex separation mechanism, more complex, in

**Table 1** Characteristic properties of conventional (TLC) and high-performance (HPTLC) thin-layer chromatographic separations

Parameter	TLC	HPTLC
Plate dimensions (cm)	20 × 20	10 × 10 or 10 × 20

fact, than column liquid chromatography. The mobile phase velocity varies with migration distance and is subject to local fluctuations due to the presence of a vapor phase and from solvent demixing. In addition, in TLC the mobile phase normally penetrates a dry layer. The flow of solvent at the developing front is generally unsaturated and the speed with which the front moves depends on the experimental conditions. Capillary forces are stronger in the narrow interparticle channels, leading to a more rapid advance of the mobile phase. Larger pores below the solvent front are filled at a slower rate resulting in an increased thickness of the mobile phase layer. If the vapor phase and mobile phase are not in equilibrium, evaporation will cause a loss of mobile phase from the layer surface and a decrease in the solvent front velocity. On the other hand, the dry layer ahead of the solvent front progressively adsorbs vapor, filling some of the pores and interparticle channels, and increasing the apparent velocity with which the solvent front migrates. Various kinds of sandwich chambers, which either eliminate or minimize contact of the plate surface with the vapor phase, offer reasonable control of the mobile phase velocity.

Separations performed with mixed solvents of different solvent strength may form multiple solvent

fronts. As the mobile phase moves through the layer, it becomes depleted in the solvent with the highest affinity for the stationary phase. Eventually, a secondary front is formed that separates the bulk mobile phase from mobile phase now totally depleted in the solvent selectively adsorbed by the stationary phase. For a mobile phase consisting of  $n$  solvents, as many as  $n + 1$  solvent fronts are possible. This process is referred to as solvent demixing and results in sample components moving in regions of different solvent strength and selectivity. Under these conditions, retention is no longer easily related to the bulk mobile phase composition. Sample zones close to a secondary front are often focused into narrow bands with a different shape to neighboring zones, which allows demixing conditions to be identified. Solvent demixing occurs more commonly in developing chambers with an unsaturated atmosphere.

### Capillary Flow

The common methods of development in TLC employ capillary forces to transport the mobile phase through the layer. These weak forces arise from the decrease in free energy of the solvent as it enters the porous structure of the layer. The velocity at which

the solvent front moves through the layer is a function of the distance of the front from the solvent entry position and declines as this distance increases. There are two consequences of this effect: (1) the mobile phase velocity varies as a function of time (and migration distance) and (2) the mobile phase velocity is established by the system variables and is otherwise beyond experimental control. In the absence of a significant exchange of solvent flux with the vapor phase the position of the solvent front with respect to time is adequately described by eqn [1]

$$(Z_f)^2 = \kappa t \quad [1]$$

and after differentiation, the velocity of the solvent front by

$$u_f = \kappa / 2Z_f \quad [2]$$

where  $Z_f$  is the distance of the solvent front position above the solvent level in the developing chamber,  $\kappa$  the velocity constant ( $\text{cm}^2 \text{s}^{-1}$ ),  $t$  the time from contacting the layer with the solvent, and  $u_f$  the solvent front velocity. In the absence of equilibrium, rather complex correction factors must be applied to eqn [1]. For a given set of experimental conditions the velocity constant is related to the characteristic properties of the mobile and stationary phases by eqn [3]

$$\kappa = 2K_0 d_p (\gamma / \eta) \cos \theta \quad [3]$$

where  $K_0$  is the permeability constant of the layer,  $d_p$  the average particle size,  $\gamma$  the surface tension,  $\eta$  the viscosity of the mobile phase, and  $\theta$  the contact angle between the mobile phase and the layer. The permeability constant is dimensionless and takes into account the effect of porosity on the permeability of the layer and the bulk liquid velocity to the solvent front velocity. The permeability constant varies little for well-prepared layers and has typical values of  $1\text{--}2 \times 10^{-3}$ . Higher velocities are achieved by using layers of a relatively large particle size with mobile phases that fully wet the layer and have a favorable surface tension to viscosity ratio. Increasing the average particle size of the layer increases the mobile phase velocity at the expense of broader chromatographic zones requiring that a compromise is struck between the two effects. In addition, the velocity constant varies linearly with the ratio of the surface tension to viscosity of the mobile phase. Consequently, solvents that maximize this ratio (and not just optimize one of the parameters) are required for fast and efficient separations. Virtually all solvents fully (or very nearly so) wet silica gel and

polar chemically bonded layers with a contact angle close to zero ( $\cos \theta = 1$ ). This is not the case for aqueous mobile phases on chemically bonded layers prepared from reagents with long-chain alkyl groups. To make these layers completely compatible with aqueous phases for reversed-phase separations a sorbent of larger particle size with a lower bonding density of alkyl groups is used. Separation times can be relatively long depending on the composition of the mobile phase (Figure 2).

There are two features of importance when using eqns [1] and [2] to represent the flow characteristics of the mobile phase through the layer. The velocity constant depends on the identity of the mobile phase, the characteristic properties of the layer, the layer thickness, and the state of equilibrium between solvent vapors in contact with the layer and the bulk solvent moving through the layer. The velocity constant is, in fact, a system constant, only invariant for a given set of experimental conditions. The bulk mobile phase velocity representing saturated flow through the region occupied by the sample zones is moving at a lower velocity than the solvent front velocity. A value of  $0.8u_f$  is taken as a reasonable estimate of the bulk mobile phase velocity for calculation of the effect of mobile phase velocity on zone broadening.

The system conditions that affect the mobile phase velocity are outlined above, but this does not answer the question of whether capillary forces are strong enough to enable mobile phase velocities close to optimum under typical conditions. The optimum

**Figure 2** Plot of the time required for the solvent front to migrate 5 cm on a Merck HPTLC RP-18 WF254s layer with aqueous mobile phases of different composition. **Figure 3** Relationship between the solvent-front migration distance for dichloromethane on an HPTLC silica gel layer as a function of time for different experimental conditions. Identification: (1) forced flow development at  $u_{\text{opt}}$ ; (2) capillary flow in a saturated chamber; (3) capillary flow in a saturated chamber with a covered layer (sandwich chamber); and (4) capillary flow in an unsaturated chamber.

mobile phase velocity for a separation can be established by forced flow development (see next section). This velocity is considerably higher than the mobile phase velocity obtained by use of capillary flow under different experimental conditions (Figure 3). This figure illustrates the three cardinal deficiencies of capillary flow systems: (1) capillary forces are inadequate to achieve the desired optimum mobile phase velocity; (2) the mobile phase velocity declines as the solvent front migration distance increases and is increasingly less favorable for maintaining acceptable chromatographic efficiency as the solvent front moves higher up the layer; and (3) the mobile phase velocity is a complex function of the system conditions and can only be reproduced by careful attention to experimental details.

### Forced Flow

Forced flow separations overcome the principal deficiencies of capillary flow separations by establishing a constant and optimum mobile phase velocity. Forced flow separations require specially designed developing chambers exploiting either centrifugal or pneumatic forces to drive the mobile phase through the layer. Centrifugal methods are more popular for preparative-scale separations and have been little used for analysis. The preferred approach for analytical separations is to seal the open face of the layer by contact with a flexible membrane, under hydraulic pressure, and deliver the mobile phase to

the layer with a constant-volume, reciprocating-piston pump. For as long as the difference between the hydraulic seal and the mobile phase inlet pressure is sufficient, the position of the solvent front at any time after the start of development is described by  $Z_f = u_f t$ . The mobile phase velocity ( $u_f$ ) no longer depends on the contact angle and there are no restrictions on solvent selection for reversed-phase layers, unlike capillary flow systems. A disadvantage of forced flow is the possible appearance of several fronts during the development due to the difficulty of displacing air from the dry layer by the mobile phase and due to solvent demixing. Sample zones moving in the disturbing zone, a region of the mobile phase containing microbubbles of air, or passed over by it, are often distorted and difficult to record by densitometry. Various operating procedures are available to eliminate or minimize problems caused by the disturbing zone. For example, an initial development with a weak mobile phase to displace trapped air from the layer before starting the separation or by using a backpressure regulator to increase the solubility of air in the mobile phase.

### Electroosmotic Flow

Electroosmotic flow has emerged as a viable alternative transport mechanism to pressure-driven flow in column chromatography. Benefits include a plug-flow profile (reduced transaxial contributions to zone broadening) and a mobile phase velocity that is independent of the column length and particle size. The electroosmotic-driven flow is governed by the dielectric constant of the mobile phase, the zeta potential at the stationary phase/mobile phase interface, and the applied electric field. The efficiency obtainable is limited by double layer overlap or radial dispersion induced by inefficient heat dissipation.

The current status of electroosmotic-driven flow in TLC is probably more confusing than reassuring, although recent studies have brought some enlightenment to this approach. Early studies of electroosmotic flow in vertically mounted layers using solvents of low polarity as the mobile phase are now believed to be the result of thermal effects. Enhanced flow results from forced evaporation of the mobile phase from a solvent-deficient region at the top of the layer. Because of drainage in vertically mounted layers, electrical resistance is highest at the top of the layer, and the increase in heat production drives the evaporation of solvent, pulling additional solvent through the layer. True electroosmotic flow was demonstrated in horizontally mounted layers at modest field strengths ( $<1 \text{ kV cm}^{-1}$ ) with mobile

phases of suitable dielectric constant. Movement of the mobile phase toward the layer surface competes with electroosmotic flow along the layer. The voltage and buffer concentration must be optimized to minimize either excessive flooding or drying of the layer to avoid degradation of the separation quality. Many questions remain unanswered at this time. For example, which solvents to use, the necessity to impregnate the layer with solvent containing ions as current carriers, the effect of local heating on zone profiles, the effect of binder chemistry on flow characteristics, and mass transfer properties. Comprehensive studies of zone broadening are conspicuous by their absence and the future of electroosmotic-driven flow in TLC remains a matter for conjecture.

## Retardation Factor

The fundamental parameter used to characterize the position of a sample zone in a thin-layer chromatogram is the retardation factor, or  $R_F$  value. It represents the ratio of the distance migrated by the sample compared to the distance traveled by the solvent front, and for linear development is given by

$$R_F = Z_X / (Z_f - Z_o) \quad [4]$$

where  $Z_X$  is the distance traveled by the sample from its origin,  $(Z_f - Z_o)$  the distance traveled by the mobile phase from the sample origin,  $Z_f$  the distance traveled by the solvent front measured from the mobile phase entry position (the solvent level at the start of the separation), and  $Z_o$  the distance from the sample origin to the position used as the origin for the mobile phase (see Figure 4). The boundary conditions are  $1 \geq R_F \geq 0$ . When  $R_F = 0$ , the sample remains at the origin, and for  $R_F = 1$ , the sample migrates with the solvent front and does not interact with the stationary phase.  $R_F$  values are calculated to two decimal places or expressed as whole numbers, as  $hR_F$  values, equivalent to  $100R_F$ .

Systematic errors in determining  $R_F$  values result from the difficulty in locating the exact position of the solvent front. The thermodynamic solvent front, which may be slightly lower than the visible solvent front for unsaturated flow, can be determined by using an unretained substance as a solvent-front marker. The repeatability of  $R_F$  values can be improved using the saturation grade of the developing chamber to interconvert observed  $R_F$  values between different chamber designs. When the samples are available as standards, it is common practice to separate the standards and samples in

**Figure 4** Illustration of the measurements used to calculate the retardation factor and variation of the plate height with solvent front migration distance.

the same system for identification purposes. In surveillance programs, the simultaneous separation of appropriate standard substances is used to improve the certainty of identification by correcting observed  $R_F$  values to standard  $R_F$  values for automated library searches. Using the mean list method, for example, all substances that migrate in a  $R_F$  window, which might be confused, are ranked and compared across a number of separation systems. If the separation systems are complementary, the list of possible substances that might be confused will become shorter as an increasing number of substances fall outside the identification window for the unknown. Eventually, only a handful of possible substances remain on the list, at which point suitable selective separation and spectroscopic techniques are used to confirm the identification of the unknown.

The  $R_F$  value is not related directly to the distribution properties of the separation system. The  $R_M$  value is used in studies that attempt to correlate migration properties with solute structure. The  $R_M$  value is equivalent to the ratio of the residence time of the solute in the stationary and mobile phases, and is formally equivalent to the retention factor ( $\log k$ ) in column liquid chromatography. It is calculated from the  $R_F$  value by

$$R_M = \log [(1 - R_F)/R_F] \quad [5]$$

## Zone Broadening and the Plate Height Equation

Zone dimensions in the direction of development in modern TLC are usually symmetrical, and their profiles recorded by densitometry are Gaussian to a good approximation. The average plate height ( $H_{\text{obs}}$ ) and plate number ( $N_{\text{obs}}$ ) can be calculated directly from the chromatogram as

$$H_{\text{obs}} = w^2/aZ_X \quad [6]$$

$$N_{\text{obs}} = a(Z_X/w)^2 \quad [7]$$

where  $w$  is the peak width at the base (when  $a = 16$ ) or the peak width at half-height ( $a = 5.54$ ). The zone migration distance,  $Z_X$ , is equivalent to  $R_F(Z_f - Z_o)$ . In TLC each separated zone migrates a different distance, the opposite of separations by column chromatography. For column chromatography, it is reasonable to consider the plate height as a system property with an approximately constant value for all solutes with similar diffusion coefficients. In TLC, individual zones only experience those theoretical plates through which they travel and, therefore, the average plate height and plate number depend on the zone migration distance. In addition, an average value is used to indicate that the mobile phase velocity varies throughout the chromatogram when capillary flow conditions are used and individual zones migrate through regions of different local efficiency. Thus, the average plate height and the observed plate height in the chromatogram are identical. For the same reason, the average plate height depends on the distance between the sample application position and the mobile phase entry position or solvent level for the layer ( $Z_o$ ). Selecting higher values of  $Z_o$  results in zones being forced to migrate with a lower mobile phase velocity, which results in further zone broadening.

A plot of the average plate height as a function of the solvent-front migration distance, **Figure 5**, reveals several important features of zone broadening with capillary flow conditions. First, there is a dominant relationship between the solvent-front migration distance, the average particle size for the layer, and the separation performance. Layers of a small average particle size (HPTLC) afford compact zones if the solvent-front migration distance does not exceed  $\sim 5$ – $6$  cm. At longer solvent-front migration distances, layers of a larger average particle size (TLC) are more efficient. This contrary finding is easily explained by the relative permeability of the layers. The mobile phase velocity for the HPTLC layers declines rapidly with the solvent-front migration distance until eventually zone broadening

**Figure 5** Variation of the average plate height as a function of the solvent front migration distance for HPTLC and TLC layers. (Reprinted with permission from Poole CF and Poole SK (1995) Multidimensionality in planar chromatography. *Journal of Chromatography A* 703: 573–612; © Elsevier.)

exceeds the rate of zone center migration. It is futile to use solvent-front migration distances longer than 5–6 cm for HPTLC layers for this reason. For the more permeable TLC layers the mobile phase velocity is higher for longer distances. As expected, the minimum in the plate height is shifted to longer solvent-front migration distances for the TLC layer, but the intrinsic efficiency, measured by the minimum plate height, is more favorable for the HPTLC layer. When the development distance is optimized the separation performance of conventional and high-performance layers are not very different. The virtues of HPTLC layers are that it requires a shorter migration distance to achieve a given efficiency resulting in faster separations and more compact zones, which are easier to detect by scanning densitometry.

For forced flow separations a constant plate height independent of the solvent-front migration distance is obtained (see **Figure 5**). The minimum plate height for capillary flow is always greater than the minimum for forced flow at the optimum mobile phase velocity. The limited range of mobile phase velocities ( $0.02$ – $0.005 \text{ cm s}^{-1}$ ) for capillary flow prevents the optimum performance of the layers from being realized. At the mobile phase optimum velocity, forced flow affords zones that are more compact and have shorter separation times compared with capillary flow. In addition, for forced flow the intrinsic efficiency increases with a reduction of the average particle size for the layer.

For forced flow conditions a direct comparison with column separations is possible within the framework of the reduced parameter model. The

**Table 2** Common terms used in the reduced parameter model for forced flow separations

Parameter	Description
Reduced plate height	Number of particles to a theoretical plate $h = H_{\text{obs}}/d_p$
Reduced velocity	Rate of flow of the mobile phase relative to the rate of diffusion of the solute over one particle diameter $v = ud_p/D_M$
Flow resistance parameter	Measure of the resistance to flow of the mobile phase $\phi = \Delta P d_p^2 t_M / \eta L$
Separation impedance	Measure of the difficulty of achieving a certain performance ( $E_{\text{min}}$ corresponds to optimum performance) $E = h^2 \phi$
Knox equation	$h = A v^{1/3} + B/v + C v$ $A$ = measure of the uniformity and packing density of the layer; $B$ = measure of the extent to which solute diffusion is hindered by the presence of particles in the layer and the structure of the layer; $C$ = reflects the efficiency of mass transfer between the streaming portion of the mobile phase and the stationary phase

$d_p$  = particle size,  $u$  = mobile phase (constant) velocity,  $D_M$  = mobile phase solute diffusion coefficient,  $\Delta P$  = pressure drop across the layer,  $t_M$  = retention time of an unretained compound (or compound moving with the solvent front),  $\eta$  = mobile phase viscosity,  $L$  = development length.

**Figure 6** Plot of the reduced plate height against the reduced velocity for a typical HPTLC layer and HPLC column. (Reprinted with permission from Poole CF (1999) Planar chromatography at the turn of the century. *Journal of Chromatography A* 856: 399–427; © Elsevier.)

reduced parameters are dimensionless and calculated from characteristic column and layer properties as indicated in Table 2. Figure 6 illustrates the variation of the reduced plate height ( $h$ ) as a function of the reduced mobile phase velocity ( $v$ ) for an HPTLC silica gel layer with forced flow conditions, for a typical column. The optimum reduced mobile phase velocity is shifted to a lower value compared with that for the column and the minimum in the reduced plate height ( $h \approx 3.5$ ) is higher than typical values for a good column ( $h \approx 2.0$ – $2.5$ ). Also, at higher reduced mobile phase velocities the reduced plate height for

the layer is significantly larger than for the column. Consequently, separations by forced flow will be slower than those achieved with typical columns, and fast separations at high flow rates will be less efficient.

The reasons for the difference between columns and layers can be deduced by interrogating the coefficients of the Knox equation (see Table 2) providing the best fit to the experimental data (Table 3). The term ( $B/v$ ) is a measure of the contribution of longitudinal diffusion to the plate height. The magnitude of the  $B$  coefficient is related to the solute diffusion coefficient and is expected to have similar values for columns and layers. The ( $A v^{1/3}$ ) term is a measure of flow anisotropy within the streaming part of the mobile phase and is related to the packing density and homogeneity of the layer. For HPTLC layers the  $A$  coefficients are smaller than for typical columns, indicating that the layers are homogeneously packed and have a good packing structure. TLC layers are not as homogeneously packed, perhaps because of the greater difficulty of preparing layers from silica gel with a wider particle-size distribution. The ( $C v$ ) term is a measure of the resistance to mass transfer between the stationary phase and the streaming portion of the mobile phase. Typical values of the  $C$  coefficient for columns are much smaller than for layers. The large resistance to mass transfer term might arise as a result of restricted diffusion within the porous particles or from partial blocking of the intraparticle channels, owing to the presence of binder.

Some expectations for forced flow separations are summarized in Table 4. For a normal development distance of 18 cm a modest increase in performance

**Table 3** Characteristic properties of silica gel precoated layers and columns

Parameter	Layers		Column
	High performance	Conventional	High performance
Porosity			
Total	0.65–0.70	0.65–0.75	0.8–0.9
Interparticle	0.35–0.45	0.35–0.45	0.4–0.5

(a maximum plate number of 8000) in a credible time of 9 min is achieved compared with typical results for capillary flow (plate number < 5000 in  $\sim 25$ –45 min). Really significant increases in efficiency are achieved

only by the use of longer layers at the expense of separation time. The optimum mobile-phase velocity is sufficiently low that compared with columns the pressure drop remains modest. Fast separations on HPTLC layers result in low efficiency, and high pressures are required if long development distances are used. These conditions are not useful for most separations, especially because layers enable separations to be performed in parallel, so the relative time per separation is not adversely impaired compared with those of other separation techniques. If a relatively large plate number is to be achieved then high pressures are required. Reducing the particle size from an average of 5 to  $3 \mu\text{m}$  results in significantly improved efficiency with favorable separation times, but is more demanding in terms of operating pressure. No benefits are expected from the use of conventional layers for forced flow separations.

### Layer Characteristics

Layers have a heterogeneous structure consisting of the sorbent particles, held together by added binder, with other possible additives, such as a fluorescence indicator for visualization of ultraviolet-absorbing compounds. Representative values for the kinetic properties of precoated silica gel layers are summarized in **Table 3**. The similar values for the interparticle porosity of columns and layers suggests that their packing density is similar, whereas the significant difference in the total porosity and intraparticle porosity indicates that the intraparticle volume of the layers is substantially smaller. A significant amount of the binder used in stabilizing the layers must be

contained within the pores. The difference in flow resistance properties of the HPTLC and TLC layers might arise from the presence of a greater portion of fine particles in the HPTLC layer compared with the TLC layer, reflecting the fact that HPTLC layers are prepared from particles of a smaller average particle size initially. Layers with a narrower particle size distribution but similar average particle size could lead to a further improvement in capillary flow separations on HPTLC layers. The small difference between apparent average particle sizes for HPTLC and TLC layers is the origin of the small difference between the minimum plate height for modern layers. Historically, conventional layers afforded poorer separations because they were prepared from sorbents with a significantly wider particle size distribution. Contemporary TLC layers are prepared from particles of smaller average size and narrower particle size distribution compared with a decade ago, and this is reflected in their improved separation performance.

### Multiple Development

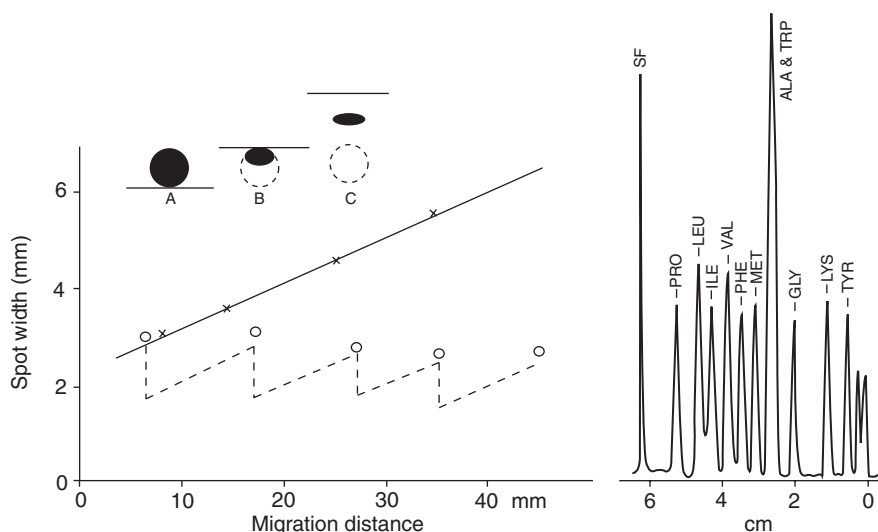

Multiple development techniques (Table 5) provide a complementary approach to forced flow for minimizing zone broadening. All multiple development techniques employ successive repeated development of the layer in the same direction with the removal of mobile phase between developments. Approaches differ in the changes made at each development, such

as the solvent front migration distance, time of development, and mobile phase composition, and in the total number of developments employed for the separation. By varying the mobile phase composition at some or all development steps, a simple means of generating solvent gradients is obtained. The separation can be recorded as a single chromatogram using incremental multiple development with a reverse gradient of solvent strength (e.g., automated multiple development or AMD); with an increasing gradient of solvent strength the mixture composition is inferred by scanning intermediate steps in the development sequence where the resolution of each group of components is optimized, even if at a later development step they are merged again.

A unique feature of multiple development techniques is the zone focusing mechanism that is exploited to counteract the normal zone broadening that occurs in each successive development. Each time the solvent front traverses the stationary sample zone, the zone is compressed in the direction of development (Figure 7). The compression occurs because the mobile phase contacts the bottom edge of the zone first; here the sample molecules start to move forward before those molecules still ahead of the solvent front. When the solvent front has reached beyond the zone, the focused zone migrates and is subject to the normal zone broadening mechanisms. Both theory and experiment indicate that beyond a minimum number of development steps zone widths converge to a constant value that is roughly

**Table 5** Multiple development techniques

<i>Method</i>	<i>Features</i>
Multiple chromatography	<ul style="list-style-type: none"> <li>• Fixed development length</li> <li>• Same mobile phase for each development</li> <li>• The number of developments can be varied</li> </ul>
Incremental multiple development	<ul style="list-style-type: none"> <li>• Variable development length               <ol style="list-style-type: none"> <li>(a) First development is the shortest</li> <li>(b) Each subsequent development is increased by a fixed distance</li> <li>(c) Last development length corresponds to the maximum useful development distance</li> </ol> </li> <li>• Same mobile phase for each development</li> <li>• The number of developments can be varied</li> </ul>
Two-dimensional chromatography	<ul style="list-style-type: none"> <li>• Sample applied at corner of layer</li> <li>• Two developments used, with the direction of the second being orthogonal to the first</li> <li>• Requires that the retention mechanisms for the two developments are complementary</li> </ul>
Increasing solvent strength gradients	<ul style="list-style-type: none"> <li>• Fractionates sample into manageable subsets</li> <li>• Optimizes separation of each subset</li> <li>• Complete separation of all components is not achieved at any segment in the development sequence</li> </ul>
Decreasing solvent strength gradients (AMD)	<ul style="list-style-type: none"> <li>• Uses incremental multiple development</li> <li>• First development employs the strongest solvent with a weaker solvent for each subsequent step</li> <li>• Final separation recorded as a single chromatogram</li> </ul>

**Figure 7** Illustration of the zone focusing mechanism (left) and its application to the separation of a mixture of PTH-amino acid derivatives (right). The broken line on the left-hand side of the figure represents the change in spot size due to the expansion and contraction stages in multiple development and the solid line depicts the expected zone width for a zone migrating the same distance in a single development. (Adapted with permission from Poole CF, Poole SK, Fernando WPN, *et al.* (1989) *Journal of Planar Chromatography* 2: 336–345.)

independent of migration distance. The position of a zone in multiple chromatography (constant development length) is given by

$$R_{F,p} = 1 - (1 - R_F)^p \quad [8]$$

and in incremental multiple development (each successive development distance is increased by a constant amount) by

$$R_{F,p} = 1 - (1 - R_F)[\{1 - (1 - R_F)^p\}/pR_F] \quad [9]$$

where  $R_{F,p}$  is the apparent  $R_F$  value after  $p$  successive developments and  $R_F$  is the  $R_F$  value in the first development. The prediction of zone widths is more complicated than for zone positions. Inexact phenomenological models and computer simulations are used for this purpose. The theory developed so far is for isocratic mobile phases and is not applicable to solvent gradients, although the same general phenomenon of a roughly constant zone width is observed in optimized separations by automated multiple development. For difficult separations by capillary flow, multiple development is the general strategy used to increase the zone capacity.

## Resolution

The resolution,  $R_S$ , between two separated zones in TLC is defined as the ratio between the separation of

the zone centers and the average zone widths

$$R_S = 2(Z_{X2} - Z_{X1})/(w_{b1} + w_{b2}) \quad [10]$$

where  $w_b$  is the width of the zone at its base and the subscripts 1 and 2 refer to the positions of the zones in the chromatogram ( $Z_{X2} > Z_{X1}$ ). To achieve a certain separation it is necessary to know how the resolution varies with the experimental parameters, such as the layer efficiency, the ratio of the equilibrium constants for the separation process (or selectivity), and the position of the zones in the chromatogram. There is no exact relationship for this purpose, but qualitatively eqn [11] and Figure 8 provide an adequate qualitative description of the separation process for capillary flow conditions

$$R_S = [\sqrt{(N_1 R_{F2})/4}][(k_1/k_2) - 1][1 - R_{F2}] \quad [11]$$

where  $N_1$  is the plate number the zones would have passed over if they migrated to the solvent front position and  $k$  is the retention factor. Resolution increases with efficiency in a manner that depends linearly on the  $R_F$  value. Relatively small changes in selectivity have a large impact on the ease of obtaining a separation, since the total plate number available is never very large. Separations by TLC are easy when  $(R_{F2} - R_{F1}) > 0.1$ , and very difficult or impossible for  $(R_{F2} - R_{F1}) < 0.05$ , in the region of the optimum  $R_F$  value for the separation. The effect of zone location on resolution shows the opposite behavior to layer

**Figure 8** Variation of the resolution of two closely migrating zones as a function of the  $R_F$  value of the faster moving zone.

quality. At large values of  $R_{F2}$ , the term  $(1 - R_{F2})$  is small and resolution falls to zero at  $R_{F2} = 1$ . Differentiation of eqn [11] indicates that the maximum resolution of two difficult to separate zones will occur at an  $R_F$  value of  $\sim 0.3$ . From **Figure 8**, it can be seen that resolution does not change significantly for  $R_F$  values between 0.2 and 0.5; and within this range, the resolution is greater than 92% of the maximum value (75% between  $R_F = 0.1$  and 0.6). This is the target  $R_F$  range for those components most difficult to separate in a mixture. Of course, to create sufficient separation capacity to separate complex mixtures, only the sample components most difficult to separate will be positioned in the optimum range, with substances easier to separate outside of it, since the optimum resolution region has a limited zone capacity.

Resolution in forced flow separations is not restricted by the same factors that apply to capillary flow. Resolution increases almost linearly with the solvent-front migration distance and is highest at the optimum mobile phase velocity. There is no theoretical limit to resolution for forced flow separations; the upper bounds are established by practical constraints, such as plate length, separation time, and inlet pressure.

## Zone Capacity

The potential of a chromatographic system to provide a separation can be estimated from its zone capacity, sometimes referred to as the separation number or spot capacity in TLC. The zone capacity envisages the arrangement of the zones in a chromatogram as being similar to a string of beads,

**Table 6** Experimental or theoretical zone capacity for different separation conditions

Separation mode	Dimensions	Zone capacity
<i>(i) Predictions from theory</i>		
Capillary flow	1	$< 25$
Forced flow	1	$< 80$ (up to 150 depending on pressure limit)
Capillary flow	2	$< 400$
Forced flow	2	Several thousand
<i>(ii) Experimental observations</i>		
Capillary flow	1	12–14
Forced flow	1	30–40
Capillary flow (AMD)	1	30–40
Capillary flow	2	$\sim 100$
<i>(iii) Predictions based on (ii)</i>		
Forced flow	2	$\sim 1500$
Capillary flow (AMD)	2	$\sim 1500$

each bead touching its neighbor, with no unoccupied space between the beads. In practice, the zone capacity leads to an inflated estimate of the real separation capacity, since real chromatograms do not consist of equally spaced zones. It does provide, however, a plausible guide for comparison of the separation potential of different thin-layer techniques. In addition, it affords an indication of the possibility of separating a given mixture, for unless the zone capacity exceeds the number of sample components by a significant amount, the separation will be difficult to impossible to achieve.

The zone capacity is defined as the number of spots completely separated with  $R_s = 1$  between  $R_F = 0$  and  $R_F = 1$ . Most methods of calculation, however, use approximate models for either the form of the chromatogram, such as a geometric increase in zone size throughout the chromatogram, or attempt to estimate the increase in zone size by a theoretical model. No approach is completely satisfactory. Some represented results from theory and experiment are summarized in **Table 6**. Results from theory are probably too high and represent an upper bound to the zone capacity. Experiment indicates a zone capacity of  $\sim 12$ –14 for a single development with capillary flow. This rises to  $\sim 30$ –40 for forced flow conditions. Automated multiple development with capillary flow provides a similar zone capacity to forced flow separations. Two-dimensional TLC employing different retention mechanisms for each orthogonal separation provides a significantly larger zone capacity than any of the one-dimensional development methods. This accounts for the continuing interest in this technique. In theory, the zone capacity becomes very large for two-dimensional TLC if forced flow or multiple

development is used for the orthogonal separations, but this has not been confirmed by experiment.

## Introduction

One of the most important tools when performing thin-layer chromatography (TLC) is the thin-layer plate itself. It is often overlooked as not important since it is just removed from the box as a prepared TLC plate, spotted and developed. But considerable technology has gone into the manufacturing of the TLC sorbents, the binders, the supports, and the plating machinery to make a reproducible product suitable for the market. If the layer is not well made, it would be possible to see thickness differences, bubbles in the dried layer, crooked solvent fronts, and impurities at the solvent front – all of which can contribute to poor, nonreproducible results. What is desired is an even, flat layer, free of imperfections and impurities. This article will describe some of the aspects of the plate-making process including details of the sorbents, the binders, and the supports. Details of the manufacture, although of interest, are proprietary, and as such cannot be discussed here.

## Before the Prepared TLC Plate

Prior to the availability of the prepared thin-layer plates, anyone wanting to do TLC had to make their own plates. This is a laborious task, involving cleaning glass plates, putting them on a special holder, making up a slurry of the sorbent with water (of a

definite consistency), putting this slurry in an applicator, and then drawing this applicator across the plates at a controlled, even rate. A gate could be set on the applicator to allow different thicknesses of thin layers to be deposited on the glass plates.

After a few minutes the slurry began to set, turning from a wet, watery look to a matt finish as the binder (discussed below) begins to hydrate. The plate was then allowed to air dry, and finally dried in an oven at 100°C for 30 min to remove remaining moisture.

Although time consuming, it was the only way people interested in TLC could get the thin-layer plates for their work. Fortunately, the manufacturers of the sorbents realized that supplying a precoated plate would be more cost-efficient and more reproducible for the users. In the early 1960s, the first prepared TLC plates came onto the market.

## The Sorbents Used in TLC

### Silica Gel (Silica)

The sorbent used the most for TLC work is silica gel. It is an amorphous, porous matrix made by the addition of acid to a sodium silicate solution. With proper control of the hydration process, the silica gel will cross-link to form a hydrogel, which is then washed and dried, yielding a product with pore sizes of  $\sim 60 \text{ \AA}$  and a surface area of  $\sim 500 \text{ m}^2 \text{ g}^{-1}$ . Other pore sizes/surface area silica gels can be made by changing the conditions of the hydrolysis, but the  $60 \text{ \AA}$  silica gel has been the standard used in TLC for

development is used for the orthogonal separations, but this has not been confirmed by experiment.

## Introduction

One of the most important tools when performing thin-layer chromatography (TLC) is the thin-layer plate itself. It is often overlooked as not important since it is just removed from the box as a prepared TLC plate, spotted and developed. But considerable technology has gone into the manufacturing of the TLC sorbents, the binders, the supports, and the plating machinery to make a reproducible product suitable for the market. If the layer is not well made, it would be possible to see thickness differences, bubbles in the dried layer, crooked solvent fronts, and impurities at the solvent front – all of which can contribute to poor, nonreproducible results. What is desired is an even, flat layer, free of imperfections and impurities. This article will describe some of the aspects of the plate-making process including details of the sorbents, the binders, and the supports. Details of the manufacture, although of interest, are proprietary, and as such cannot be discussed here.

## Before the Prepared TLC Plate

Prior to the availability of the prepared thin-layer plates, anyone wanting to do TLC had to make their own plates. This is a laborious task, involving cleaning glass plates, putting them on a special holder, making up a slurry of the sorbent with water (of a

definite consistency), putting this slurry in an applicator, and then drawing this applicator across the plates at a controlled, even rate. A gate could be set on the applicator to allow different thicknesses of thin layers to be deposited on the glass plates.

After a few minutes the slurry began to set, turning from a wet, watery look to a matt finish as the binder (discussed below) begins to hydrate. The plate was then allowed to air dry, and finally dried in an oven at 100°C for 30 min to remove remaining moisture.

Although time consuming, it was the only way people interested in TLC could get the thin-layer plates for their work. Fortunately, the manufacturers of the sorbents realized that supplying a precoated plate would be more cost-efficient and more reproducible for the users. In the early 1960s, the first prepared TLC plates came onto the market.

## The Sorbents Used in TLC

### Silica Gel (Silica)

The sorbent used the most for TLC work is silica gel. It is an amorphous, porous matrix made by the addition of acid to a sodium silicate solution. With proper control of the hydration process, the silica gel will cross-link to form a hydrogel, which is then washed and dried, yielding a product with pore sizes of  $\sim 60 \text{ \AA}$  and a surface area of  $\sim 500 \text{ m}^2 \text{ g}^{-1}$ . Other pore sizes/surface area silica gels can be made by changing the conditions of the hydrolysis, but the  $60 \text{ \AA}$  silica gel has been the standard used in TLC for

many years. The active part of any silica gel surface is the Si–O–H groups (called silanols). They strongly bind polar groups on any structure allowing for differentiation and separation. Water also binds strongly with silanols, so control of moisture in the air and the solvent is important for getting reproducible results when using this type of plate. The surface pH of most silica gels is neutral (pH 7.0), allowing for the separation of neutral, acidic, and basic site compounds; hence, its wide use continues even today. There is probably no class of compounds that have not been successfully separated on silica gel layers, so the literature is easily found for any new attempts by users to applying this layer for their work.

After the initial manufacturing, the resulting large silica gel particles are crushed to a powder-like consistency. This is the fine size range found on all TLC plates today. Depending on the product to be made – whether a standard thin layer (TLC), a high-performance thin layer (HPTLC or HPTLC spherical), or a preparative layer (PLC) – the particle size range is changed to give the best in performance and plate-making ability. This is done by sieving or air classifying the crushed or spherical materials. The UTLC (ultra-thin layer) is made differently than the others and will be discussed separately. These are shown in Table 1. The cross-section of a standard TLC plate is shown in Figure 1.

### Aluminum Oxide (Alumina)

This is another metal oxide used in thin-layer applications. The chemical formula is  $\text{Al}_2\text{O}_3$ . On aluminum oxide thin-layers sorption is based on partial positive and negative charges on the surface and any water sorbed thereon. In the manufacturing process aluminum oxide can be made to have a basic surface (pH 9–10), a neutral surface (pH 7–8), or an acidic surface (pH 4–4.5). This allows for a different type of adsorption separation based solely on surface pH. Other properties of the different aluminas available for TLC are shown in Table 2. The different pore size and surface area types will also impart different separation characteristics to these sorbent layers. Layers of this sorbent are available with and without binders both organic and inorganic. A whole range of

separations have been done on alumina, particularly basic species and polyaromatic hydrocarbons.

### Other Oxides

Theoretically any metal oxide could be used as a thin-layer sorbent, but most have no specific properties that promote a unique separation or selectivity to a thin-layer plate. Infrequently, someone publishes work done on another metal oxide, but only those mentioned above are used frequently and are considered significant.

### Cellulose

This is a sorbent derived from natural sources. It is fibrous in nature, with a polymerization of 400–500 glucose units. Of course, any fiber can be broken to smaller sizes more suitable for TLC. And the native

Particle size range	5–20 $\mu\text{m}$	4–7 $\mu\text{m}$	3–5 or 6–8 $\mu\text{m}$	20–40 $\mu\text{m}$	Not applicable

fiber can also be hydrolyzed to a smaller fiber, with different properties. This latter type is usually referred to as 'microcrystalline' and is ~40–200 glucose units in length. Of course, because it is the same material used for paper, thin layers of cellulose have replaced any paper chromatography done years previously. Although the solvent migration with TLC work on cellulose is slow compared to that done on silica gel, it has a unique selectivity for many biological compounds.

Derived or coated celluloses are also available. These include acetylated, diethylaminoethyl (DEAE), polyethyleneimine (PEI). More on these will be discussed in the section Ion Exchange Layers below.

Cellulose binds very well to glass because of the fiber overlay and hydrogen bonding with the glass surface thus is often binder free. To prevent cracking when the layer is made, the thickness is usually only 0.1 mm on the analytical layer. This layer has been used to separate amino acids, antibiotics, flavonoids, peptides, and related compounds.

### Polyamide

Two versions of polyamide have found use in TLC. Both – polyamide 6 (polycaprolactam) and polyamide 11 (polyundecanamide) – are synthetic resins, each having slightly different properties. The resins have to be chilled to be effective ground for use on TLC plates. These are very good sorbents for any compounds that can hydrogen bond to the amide groups. These layers are also usually free of binders and are also manufactured with only 0.1 mm thickness.

### Bonded Silica Layers

Over the past 35 years, reversed-phase high-performance liquid chromatography (HPLC) usage has grown tremendously. The manufacturers of TLC plates thought that the chromatographer would also like to switch to various bonded reversed-phase TLC plates. TLC and HPTLC layers with RP18 (an –Si–C18 linear chain), RP8 (an –Si–C8 linear chain), RP2 (–Si–CH<sub>2</sub>–CH<sub>3</sub>), phenyl, and diphenyl (and others like propyl amino (–Si–CH<sub>2</sub>–CH<sub>2</sub>–CH<sub>2</sub>–NH<sub>2</sub>), propyl cyano (–Si–CH<sub>2</sub>–CH<sub>2</sub>–CH<sub>2</sub>–CN), and diol (–Si–CH<sub>2</sub>–CHOHCH<sub>2</sub>OH) for normal-phase separations – alternatives to pure silica gel plates) have been available for 30 years. However, perhaps only 10% of the methods previously done on silica gel have been transferred to bonded reversed-phase plates based upon their sales ratio. The reversed-phase mode does offer unique ionization control with buffers added to the much simpler methanol/water or acetonitrile/water mobile phase combinations.

Although more expensive than silica gel plates, all the bonded phases are available as HPTLC layers, so smaller plates can be used, cutting down the cost of each plate used. One company makes dual layer plates, with part of the plate being silica gel, the other part being an RP18 section. Thus, on one plate you can accomplish two modes of chromatography, first silica gel/adsorption, and then, secondly, RP18/reversed phase (or the reverse order). This is referred to as 'multidimensional' chromatography. Such a plate increases the resolving power of the chromatography because you are doing two separations using two modes rather than using only one separation and one mode.

Any of these reversed-phase plates can be useful in developing solvent systems for similar reversed-phase HPLC work, or can help determine what may not be moving through such a column. It should be remembered that only a TLC plate shows what is left at the origin with a given solvent system and hence would remain at the top of any HPLC column with this same solvent system. It is these 'remains' of samples that drastically affect HPLC column separations and column life.

### Ion Exchange

Although in the past micronized ion-exchange resins had been placed on supports for thin-layer work, these are no longer manufactured. The only ion-exchange layers available today are composed of derivatized celluloses and these are limited in number. Only PEI, DEAE, and acetylated celluloses are available. Many others (carboxymethyl, aminoethyl, and phosphorylated) are no longer manufactured. Most of these plates fell into little use with the development of ion chromatography and ion-exchange separations possible with HPLC systems. Of the bonded silica thin layers, the propylamino mentioned above is also a weak cation exchanger when used with a buffered mobile phase that can protonate the amino group.

### Chiral

Often chromatographers have asked the TLC plate manufacturers if they could make chiral TLC layers. This would allow them to determine which of the five classes of chiral columns would be most useful for their enantiomer separations. Unfortunately, such layers would be very costly since a TLC plate is used only once. Only one plate is available, typically with a 'chir' in its name. It is composed of a layer that is impregnated with proline and copper(II) ion to allow complexation of amino acids and amino alcohols for enantiomer separation. Unfortunately, this

combination only works for these two classes of compounds.

As an alternative, papers have appeared in the thin-layer literature using TLC for chiral separations by putting the chiral discrimination reagent (antibiotic, cyclodextrin, etc.) into the mobile phase. The separations work as well as if the reagents had been coated or bonded to the silica gel (or in some cases, the reversed bonded phase).

### Diatomaceous Earth (Kieselguhr)

This is often part of a thin layer in a special type of plates. Diatomaceous earth has no separation capabilities, but it can be used at the bottom end of a thin-layer plate as a spotting area. Large quantities of a dilute solution can be placed on this sorbent. When dried and the mobile phase is allowed to travel through this part of the thin-layer plate, the solvent only concentrates the components with the solvent front. Only when the sample band has crossed to the silica gel (or other sorbent) does the separation actually begin. It is essentially an on-plate concentration device. Plates with these dual zones are called 'concentration zone' or 'preconcentration' plates. They can be of immense help in placing biological samples where debris can cause problems if spotted on an active layer. This portion of the plate can also be buffered or changed to affect different capture characteristics to the plate for other on-plate clean-up. Some manufacturers use a wide pore silica gel in place of the diatomaceous earth, but the use and effect are the same. The use of this plate is shown in Figure 2.

### Thickness of Layers

The usual thickness of an analytical thin layer is 0.2–0.25 mm when put onto a glass support. Certain sorbents would crack with this layer thickness on a

glass support or if they are on a flexible support (polymer or metal). In these instances, the thickness used is reduced to 0.1 mm. Thinner layers are also available to do more sensitive analyses (by keeping the sample closer to the surface of the thin layer, so the limits of detection are increased), or for special densitometer use (the thinner layer can be penetrated better by the densitometer light to activate the fluorescent indicator or the natural fluorescence of the compounds).

Scale up of a separation is also possible in TLC. In these cases, a thicker layer would be desirable. Preparative layers (PLC) are available from manufacturer's that are 0.5, 1.0, and 2.0 mm in thicknesses. If the separation needing to be scaled up is optimized on a thinner layer, then a thicker layer can be used for the isolation of greater quantities.

Loadability for any scale up work is always related to the best separation obtainable for the critical pair, and the solubility of the compounds in the mobile phase chosen for the separation. Thus, there is no absolute answer to the amounts you can put on a single, thicker TLC plate. This must be worked out by trial and error. This is particularly true since the thicker layers generate more heat of solvation, so the interior of a developing tank will be warmer with a thicker layered plate than with a thinner one. This affects the solubility and mobility of the compounds being separated. It is often necessary to reoptimize the mobile phase for the preparative separation to account for this effect.

### The Binders

#### Calcium Sulfate

No matter what the size of the silica gel, it will not stick to a support without a binder. The binder first used to make a suitable thin layer that could be spotted, developed, and visualized was calcium sulfate hemihydrate ( $\text{CaSO}_4 \cdot \frac{1}{2}\text{H}_2\text{O}$ ). This is more

**Figure 2** Use of concentration zone thin-layer plate. Left, spotting of samples; middle, initial concentration of sample spots; right, developed sample bands.

commonly known as gypsum (the G in the name of thin-layer plates containing this binder) or plaster of Paris. It is added in about a 10% concentration to help the adhesion of the silica gel to the support. This support is most often glass, but other supports will be discussed. With this binder a layer that adheres, but is still soft to the touch and easily abraded, is produced. All operations using a G-type plate have to be done carefully so as not to inadvertently touch and disturb the thin layer. They are shipped in special boxes that separate one plate from another to maintain their integrity.

### Polymeric Binders

Because of the fragile nature of the G-type plate, manufacturers began experimenting with various water-soluble monomers/polymers (like poly(vinyl alcohol) or poly(vinyl pyrrolidone)) as suitable binders. Added to the aqueous slurry during manufacture, they cross-link during drying to form a much harder surface thin-layer plate. The binders are also relative inert to visualizers (except those that strongly char) and have little affect on the separation. The particular binders used by each manufacturer are proprietary. The binder concentrations are usually 1% or less.

As the binders are water soluble, even after they have been cross-linked by the initial heating during manufacture (and any subsequent heating for activation) they can swell when exposed to high concentrations of water in the mobile phase. If this occurs, the solution is to use a  $0.1 \text{ mol l}^{-1}$  sodium chloride solution in place of the water or to use a specially formulated plate for high water content mobile phases. These water-tolerant plates are usually designated by the manufacturers as W-type, Water tolerant, or some such description.

### Other Additives

One of the most used additives to the thin-layer plate is the fluorescent indicator. These are inorganic compounds such as alkali earth tungstate, manganese activated zinc silicate, and others (many are proprietary) and are added in a concentration of 1–3% by weight to the slurry during manufacture. Being insoluble inorganic compounds, they do not migrate with any solvents used as mobile phases on the TLC plates. After development and drying of a thin-layer plate, the layer can be illuminated with the ultraviolet (UV) wavelength that activates that fluorescent indicator. This wavelength is usually specified in the plate name, i.e., Silica gel 60 F<sub>254</sub> – activated by 254 nm UV light.

When illuminated by light of this wavelength, the indicator will fluoresce green, light blue, or white, depending on the fluorescent inorganic used. When the UV light is absorbed by a component in the layer, the indicator does not fluoresce and a dark area can be seen against the fluorescing background. Depending on the concentration of the components in the mixture, the level of fluorescence in the plate, and the intensity of the UV light, some components are more easily seen than others. Certainly, very low level components can be ‘washed out’ by the intensity of the fluorescent indicator.

It is possible to add other chemicals to the slurry when preparing a TLC plate. These might be added to adjust the pH of the layer, to aid in the separation or detection of various compounds. These are not used routinely, so should be purchased as needed to insure they are not degraded in any manner.

Among these chemicals are silver nitrate – added to allow separation of *cis/trans* isomers, particularly for lipid analyses; potassium oxalate – added to allow discrimination of polyphosphoinositides; magnesium acetate – added to help in the separation of phospholipids; ammonium sulfate – added so that the plate is self-charring (after heating); carbomer – added for the analysis of mannitol/sorbitol; and sodium hydroxide – added to improve the separation of bases and organometallics.

If in need of any of these plates, it is also possible to dip or spray these chemicals onto a plain silica gel plate (use the W-type mentioned above), dry, activate, and use. This could be done initially to see how the method works before purchasing a box of them. Often, most manufacturers of TLC plates can be called for sample plates.

## Supports

### Glass

The initial support used for all TLC work was glass. Although standard window glass is readily available and inexpensive, the borosilicate glass used for TLC manufacture has to be carefully selected. The preferred glass used is ‘float’ glass. In this manufacturing method, the molten glass is pushed through an opening onto a bed of molten tin. This produces a sheet of glass with an extremely smooth, level surface. Such a surface insures the best TLC plate will result from its use. This glass is also thinner than the usual window glass, being  $\sim 1.2 \text{ mm}$  thick. This thickness gives a satisfactory thin-layer plate and minimizes the package weight. Before the coating process, the glass is scrupulously cleaned and dried to rid it of any oils

or surface dirt that would cause an imperfect layer to be laid down.

The glass plates come in a number of sizes, and the user chooses the size needed depending on the number of samples and standards to be separated at one time. They are generally made as 20 × 20 cm prepared plates, and then the other sizes are broken down from this larger size. Some glass plates are prescored on the back of the glass, so that the large size can be broken down to smaller sizes with a minimum of effort. Cutting tools for better glass cuts of non-prescored plates are available from hobby or stained glass stores.

### Polymer and Metal

Because of the difficulty of cutting glass plates, the manufacturers came with other supports made from polymers or metals that could be more easily cut. The best know are the plastic (polyterephthalate – thickness, ~200 µm) or aluminum foil (thickness, ~100 µm) supports. As with the glass support mentioned before, the surface characteristics and cleanliness are of equal importance to producing a good thin layer. With plates using these supports, anyone can cut any size from the larger size. In doing this, the layer is moistened a bit with methanol, placed face down on a filter paper, and cut with a straight edge and razor (or X-Acto<sup>®</sup> knife), or rotary cutter. Alternatively, scissors can be used for cutting the plates to size. After cutting, the new edges should be wiped with a paper towel to eliminate fine particles from adhering to the edges of the support. This will prevent crooked solvent fronts.

### Sorbent Particle Size

The speed and resolving power are important in any chromatographic process. The driving force in TLC is capillary action through the fine matrix of the solvent mixture chosen to be best for the separation. If we can reduce the viscosity of the mobile phase, it would improve flow rate. Likewise, if we develop the plate to shorter distances then the development time will be much less. Realizing these factors from chromatographic theory, various particle size ranges shown in **Table 1** were developed over time.

These particle size changes lead to the development of an HPTLC in the mid-1970s. By reducing the average particle size on the thin-layer plate, the analysis time is reduced because a more efficient separation results. Development times are reduced to a few minutes with developing distances of 2–3 cm only. As with any separation on a TLC

plate, the optimum speed and separation are related to the viscosity of the mobile phase, but time savings on the order of three to four times are realized. Another benefit is that the limits of detection are increases because the radial diffusion on the HPTLC plates is reduced.

A summary of the performance differences in the irregular TLC and HPTLC thin-layer plates are given in **Table 3**.

Improvements in thin-layer plate technology over the past 5 years have yielded plates made not with the usual irregular silica gel but of a spherical silica gel. This also improves the speed of analysis by another factor. Some of these thin layers of spherical silica gel have been designed for direct Raman spectroscopy use.

Finally, the silica gel can be made for form as a monolith, or porous honeycomb matrix. This appears as a sheet laid down on the glass plate, so particles of silica gel are not involved. This is a truly unique matrix on which absorption separations can be performed. The layer formed of the monolithic

**Table 3** Differences in TLC and HPTLC plates

	TLC	HPTLC
Average particle size	15 µm	5 µm
Particle distribution	5–20 µm	4–7 µm
Sample size	100 µg–1 mg	100 ng–1 µg
Sample volume	0.5–5 µl	10–200 nl
Optimum spot diameter	3–6 mm	1–1.5 mm
Development distance	10–15 cm	3–7 cm
Development time	10–120 min	3–25 min
Detection limits – standard detection	5 ng	0.5 ng
Detection limits – fluorescence detection	100 pg	10 pg

### Introduction

This article covers various aspects of development and validation of methods in thin-layer chromatography. A detailed treatment of the underlying theory is given elsewhere in this encyclopedia.

### General Considerations

Thin-layer chromatography (TLC) is an offline process comprising several individual steps, which are independent in time and location. Each step, such as sample application, chromatogram development, detection (including derivatization if necessary), and evaluation is associated with a number of important parameters that can affect the final result of the analysis. The development and validation of a TLC method must not only involve a clear specification of those parameters but also an evaluation of their suitable ranges. For a given analytical task it is usually the separation step that is particularly emphasized during method development; however, the other steps may become equally important if repeatability of the qualitative result or detection limits, accuracy, and precision of quantitation are of importance.

Unlike high-performance liquid chromatography (HPLC) and gas chromatography, where the chromatographic separation generally takes place in an equilibrated system of stationary and mobile phase, TLC usually is a process during which such equilibrium is being approached and in many cases only

partially reached. As a consequence, predictability of the result in TLC is difficult and rather limited. Method development is still a widely empirical process and theoretical models or computer-aided strategies provide satisfactory solutions applicable to 'real' analytical problems only for defined systems with a strictly controlled set of parameters. Nevertheless, from a practical point of view method development in TLC can be quite simple and straight forward, if performed in a structured 'trial and error' approach. The following sections summarize such concepts.

### Defining the Analytical Goal and Experimental Approach

The starting point of any method development is a clear understanding of the analytical goal. Based on information about the nature of the sample, its size, matrix, and number of components some estimations and principal decisions about the experimental setup are made. TLC can analyze many different substances; however, it must be considered that the process includes two drying steps (following sample application and chromatogram development), which may affect the sample. Very volatile samples such as essential oils can partially evaporate from the layer. Qualitative analysis is still possible but reliable quantitation will be difficult. Large biological molecules such as proteins, which have tertiary and quaternary structures, may collapse, become insoluble, and remain at the application position. Light sensitive samples and those sensitive to oxidation require special experimental conditions in order to avoid their decomposition.

The zone capacity (also called separation number) of a chromatographic system is limited, which means that only a finite number of sample components can

silica is only 0.01 mm thick and can give a very fast, efficient separation. Use of these plates is referred to as 'UTLC'.

### Introduction

This article covers various aspects of development and validation of methods in thin-layer chromatography. A detailed treatment of the underlying theory is given elsewhere in this encyclopedia.

### General Considerations

Thin-layer chromatography (TLC) is an offline process comprising several individual steps, which are independent in time and location. Each step, such as sample application, chromatogram development, detection (including derivatization if necessary), and evaluation is associated with a number of important parameters that can affect the final result of the analysis. The development and validation of a TLC method must not only involve a clear specification of those parameters but also an evaluation of their suitable ranges. For a given analytical task it is usually the separation step that is particularly emphasized during method development; however, the other steps may become equally important if repeatability of the qualitative result or detection limits, accuracy, and precision of quantitation are of importance.

Unlike high-performance liquid chromatography (HPLC) and gas chromatography, where the chromatographic separation generally takes place in an equilibrated system of stationary and mobile phase, TLC usually is a process during which such equilibrium is being approached and in many cases only

partially reached. As a consequence, predictability of the result in TLC is difficult and rather limited. Method development is still a widely empirical process and theoretical models or computer-aided strategies provide satisfactory solutions applicable to 'real' analytical problems only for defined systems with a strictly controlled set of parameters. Nevertheless, from a practical point of view method development in TLC can be quite simple and straight forward, if performed in a structured 'trial and error' approach. The following sections summarize such concepts.

### Defining the Analytical Goal and Experimental Approach

The starting point of any method development is a clear understanding of the analytical goal. Based on information about the nature of the sample, its size, matrix, and number of components some estimations and principal decisions about the experimental setup are made. TLC can analyze many different substances; however, it must be considered that the process includes two drying steps (following sample application and chromatogram development), which may affect the sample. Very volatile samples such as essential oils can partially evaporate from the layer. Qualitative analysis is still possible but reliable quantitation will be difficult. Large biological molecules such as proteins, which have tertiary and quaternary structures, may collapse, become insoluble, and remain at the application position. Light sensitive samples and those sensitive to oxidation require special experimental conditions in order to avoid their decomposition.

The zone capacity (also called separation number) of a chromatographic system is limited, which means that only a finite number of sample components can

be baseline resolved. Assuming an optimized chromatographic system, it is generally possible in TLC to achieve baseline resolution for  $\sim 10$  components of a sample during a single development. In certain cases, such as for homologs, this number may increase. In other cases, for instance, where the components fall into extremely different substance classes, the number can decrease. If the sample is more complex, limited resolution might be still acceptable for many qualitative investigations. Fingerprint analysis of herbal drugs, often resulting in a sequence of many colored yet not fully resolved zones, is a typical example. Multiple development such as automated multiple development (AMD) or forced flow techniques such as over-pressured layer chromatography (OPLC) typically offer baseline resolution for  $\sim 25$ – $30$  and in some cases up to  $40$  sample components. If the components cover a wide polarity range, gradient techniques in combination with multiple development (AMD) or forced flow techniques (OPLC) are employed. Still higher zone capacities ( $100$ – $1000$ ) are available through two-dimensional development, where two different separation modes are combined. Although theoretically very appealing this technique is not widely used because only one sample can be analyzed per plate, complex experimental requirements have to be met (HPLC–AMD coupling), and evaluation of the chromatograms is complicated in practice.

An important decision concerns sample preparation, which in many cases can be reduced to a minimum due to the single use of the TLC plate. As long as it does not interfere with the separation the sample matrix does not have to be removed prior to chromatography. Separations can often be setup to either leave the matrix at the application position or move it close to the solvent front. Otherwise general sample treatment such as solid-phase extraction, liquid–liquid extraction must be performed. At this point, also decisions about any prechromatographic derivatization either as part of sample preparation or *in situ* on the plate immediately following sample application are made. Prior to application the sample is dissolved in a suitable solvent. It should be of low polarity when silica gel is used as stationary phase in order to keep the application zone as narrow as possible. The solvent should be of medium to high volatility to ensure proper drying of the application zone prior to chromatogram development, but at the same time avoid volume error due to unwanted evaporation. Solvents such as dimethyl sulfoxide, glycerol, and dimethylformamide or pentane, and diethyl ether are difficult to handle in TLC. For method development samples are typically prepared at an average concentration of  $1 \text{ mg ml}^{-1}$  for each

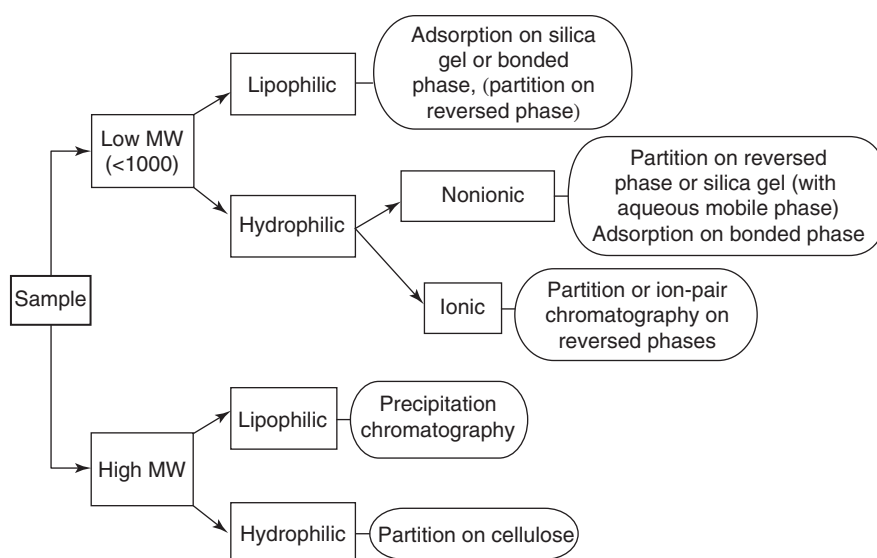

analyte. Application volumes of  $2$ – $5 \mu\text{l}$  as  $8 \text{ mm}$  bands usually ensure good detectability on high-performance thin-layer chromatography (HPTLC) plates.

In most cases methods are developed for single development in a specific chromatographic chamber. Because geometry and mode of operation (degree of saturation) can significantly affect the chromatographic result, the chamber must be selected appropriately. Although such selection generally follows the practical consideration of availability other aspects are also important. Except for initial selection of mobile phase (see below) where special chambers such as the HPTLC VARIO-Chamber (CAMAG) may be used, methods are developed using the same chamber that will later be employed during analysis. While unsaturated chambers generally yield sharper zones, saturated chambers usually give better reproducibility. If the method is intended for analysis of large numbers of samples, horizontal chambers offer the advantage of simultaneously developing HPTLC plates from two opposite edges.

## Selection of the Stationary Phase and the Separation Mode

For TLC a wide range of stationary phases is commercially available and many more materials have been reported in the literature. As in column chromatography separation can be based on different modes of interaction, including adsorption, partition, ion exchange, and complexation. The choices of stationary phases and separation modes are numerous and depend on the type of sample to be analyzed. The more information about the chemical nature of the sample components including molecular weight, functional groups,  $\text{pK}_a$  value, and solubility of all sample components is available, the easier it is to make the proper choice. A flow chart similar to that in **Figure 1** is a suitable tool for linking the separation mode for various types of samples with appropriate stationary phases.

For most samples, which are soluble in organic solvents and of low molecular weight, adsorption chromatography (also called liquid–solid chromatography, LSC) on silica gel, aluminum oxide, or other inorganic oxides is suitable. Separation is based on specific interaction of the functional groups on the surface of the adsorbent with those of the sample. Silica gel is by far the most widely used adsorbent, available in consistent quality and at comparatively low cost. Due to its ionic nature aluminum oxide offers additional selectivity; however, it is more difficult to obtain products with consistent separation properties. Therefore, separations on aluminum

**Figure 1** Selection of separation mode for a sample by thin-layer chromatography.

oxide are rather the exception. Chemically bonded phases on silica gel basis having diol, amino, or cyano functionality provide a range of complementary selectivity for separation by LSC and are often considered whenever initial attempts to solve a separation problem on silica gel have failed.

Alternatively samples of low molecular weight, particularly those of very low and very high polarity, can be separated by reversed-phase (RP) chromatography using partitioning processes. Compared to stationary phases for RP-HPLC, TLC material cannot tolerate a high water content of the mobile phase due to the limited wettability. To ensure migration of the mobile phase by capillary action the carbon load on the surface of the silica gel is therefore limited (water-wettable layers). **Table 1** summarizes principal applications of some polar and nonpolar bonded phases.

From a practical point a simple triangle scheme, which goes back to Stahl, is a convenient start for selecting a stationary phase (**Figure 2**). The scheme focuses on the interaction of the sample with both

stationary and mobile phases. For example, a very lipophilic sample requires an active adsorbent and a nonpolar (organic) mobile phase for separation in adsorption mode. If a lipophilic stationary phase such as a  $\text{C}_{18}$  reversed phase is chosen for partition chromatography, the same sample would require a very polar (aqueous) mobile phase.

Whenever possible silica gel will be the first choice as stationary phase during method development. However, silica gels of different brands may exhibit significantly different chromatographic behavior with respect to a particular analyte, mainly due to proprietary aspects of the manufacturing process. Therefore, it is important for routine methods that the continuous availability of the selected silica gel is ensured. The activity of silica gel is affected by humidity. This fact has to be considered during method development, at least to the extent that the relative humidity during chromatography is recorded. If methods are developed for quantitation and if long-term reproducibility is of concern, the TLC plates are typically cleaned prior to use in order to remove any

**Figure 2** Triangle scheme after Stahl. The corners of the triangle connect proper choices for the mobile and stationary phase based on solubility of the sample. (Adapted from Stahl E (1967) *Dünnschicht-Chromatographie – ein Laboratoriumshandbuch*. Berlin: Springer.

contamination from packaging or exposure to lab atmosphere. Cleaning is possible by development with or immersion into polar solvents such as 2-propanol or methanol and subsequent drying and re-equilibration with the relative humidity in the laboratory.

## Selection and Optimization of the Mobile Phase Composition

When a stationary phase has been chosen for a given separation problem the next step of method development is the selection of a suitable mobile phase. The choice of solvents for use as mobile phases in TLC is extremely wide because there is no interference with the detection step. However, from a practical point of view certain limitations apply. The use of toxic, obnoxious, and hazardous solvents should be avoided or at least limited. It is important that only solvents of known purity from reliable sources are used, because certain impurities can significantly affect the chromatographic result. Also, known additives, such as stabilizers in chloroform and ethers or denaturing agents in ethanol, will affect the chromatographic behavior of a solvent. For use as a mobile phase the viscosity and volatility of the liquid must be suitable.

The mobile phase should meet three general requirements: it must be able to dissolve the sample to a certain extent in order to allow its migration; it must be of appropriate 'strength' in order to obtain suitable  $R_F$  values (between 0.3 and 0.8) for the analyte; and it must provide suitable selectivity for separation of the sample components to occur. However, both strength and selectivity are not sole properties of the solvent acting as mobile phase, but also a function of the stationary phase. For example,

water has a high solvent strength on silica gel, but is very weak on a RP layer. Furthermore, the effects of these properties on the actual separation are also dependent on the nature of the sample. Nevertheless, it is common to classify solvents for use as mobile phase with a given stationary phase, such as silica gel, according to their strength and selectivity. The simplest approach is that of an eluotropic series. Solvents are arranged according to their strength, which is either based on empirical results or like  $\varepsilon^\circ$  calculated from physicochemical data such as adsorption energy (Table 2). The principal value of such an arrangement for the practitioner is that it provides guidance for adjusting the  $R_F$  values for the zones of a given chromatogram. A solvent with a higher strength will yield a higher  $R_F$  value for a given substance on a given stationary phase. Isoeluotropic solvents yield comparable  $R_F$  values. Practical selection of the mobile phase based on this concept starts with finding a suitable solvent strength to obtain  $R_F$  values around 0.3 for the substance pair to be separated. With the help of graphical presentations iso-elutotropic solvents or solvent mixtures are then selected to improve separation by changing selectivity of the chromatographic system.

More complex classification systems also involve parameters describing the selectivity of solvents. The most widely used of those is Snyder's solvent selectivity triangle. Based on the model solutes ethanol, dioxane, and nitromethane, solvents are characterized by three selectivity coordinates ( $x_e$ ,  $x_d$ ,  $x_n$ ) describing their interaction with a proton acceptor, a proton donor, and a dipolar solute. When plotted on the surface of a triangle ( $x_e + x_d + x_n = 1$ ) eight clusters, called selectivity groups, can be distinguished. Each solvent is further characterized by a solvent strength parameter  $P'$  (Table 3). Another concept

**Table 2** Properties of some commonly used solvents in TLC

<i>Solvent</i>	<i>Estimated <math>\epsilon^\circ</math> (silica gel)</i>	<i><math>\eta</math> (viscosity (cP))</i>
n-Pentane	0.00	0.23

uses the solvatochromic parameters  $\pi_1^*$  as measure of polarizability and dipolarity,  $\alpha_1$  for hydrogen bond acidity, and  $\beta_1$  for hydrogen bond basicity to classify solvents.

Although evaluation of properties of pure solvents is fairly easy, difficulties arise for accurate description of mixtures, because many parameters are neither independent nor additive, and in many cases not even available.

Regardless of which theoretical basis is adopted, practical approaches have to include a number of different solvents to cover a broad selectivity range. These solvents are initially evaluated and then combined in binary, ternary, or quaternary mixtures, if necessary including 'modifiers' for adjusting the solvent strength or to improve and optimize selectivity. Several concepts have been developed for such optimization including window diagrams, sequential simplex methods, overlapping resolution mapping, principal component analysis, and even numerical taxonomy. Although of great theoretical value most of these strategies lack general applicability for routine use because separation in TLC often relies on mixed modes of interaction and many parameters of the chromatographic system cannot be controlled.

**Table 3** Selectivity groups, solvent strength, and selectivity parameters based on Snyder's selectivity triangle (adapted from C. Poole)

<i>Solvent</i>	<i>Selectivity group</i>	<i>Solvent strength</i>		<i>Solvent selectivity</i>		
		<i>P'</i>	<i>S<sub>T</sub></i>	<i>x<sub>e</sub></i>	<i>x<sub>d</sub></i>	<i>x<sub>n</sub></i>

**Figure 3** PRISMA model after Nyiredy *et al.* The corners of the triangular base (1, 2, 3) represent solvents of different selectivities and the height at each corner (4, 5, 6) is a measure of the  $P'$  value of the individual solvents. Stronger solvents are reduced by mixing them with hexane ( $P' = 0$ ) to arrive at the strength of the weakest solvent (7, 8). The selectivity of the mobile phase system is varied by changing the proportions of the adjusted 'corner' solvents (6, 7, 8), beginning with the center point (9 = 3, 3, 3) and then moving to points close to the corners (10 = 3, 1, 1; 11 = 1, 3, 1; 12 = 1, 1, 3).

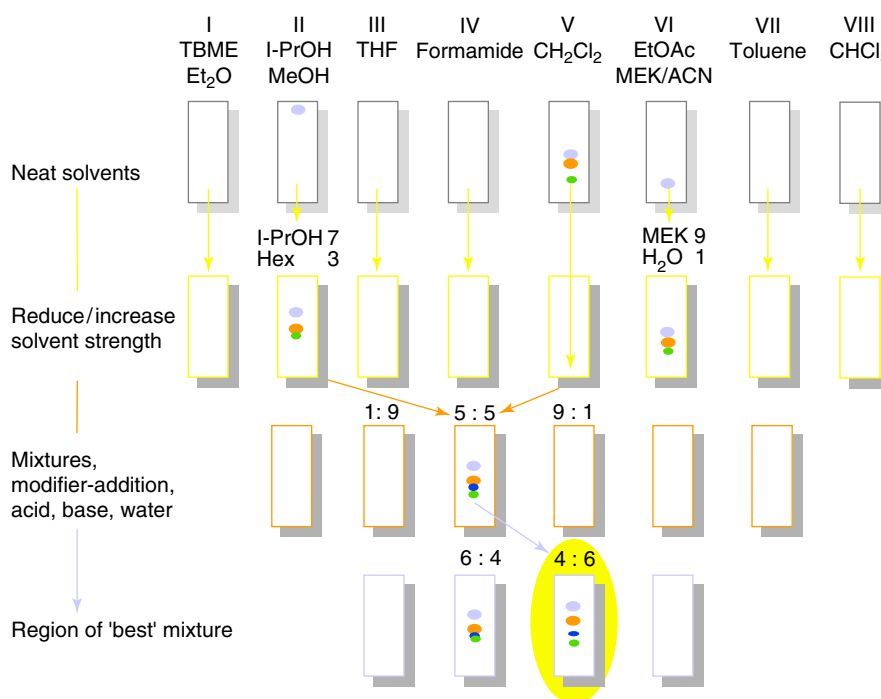

The PRISMA model (Figure 3) developed by Nyiredy and co-workers combines a theoretical basis derived from the selectivity triangle with a guided trial and error approach. In the first step, 8–10 neat solvents, representing all selectivity groups, are selected. Of those in the second step the three solvents offering best selectivity are taken for construction of the prism. The corners of the triangular base (1, 2, and 3 in Figure 3) represent the different selectivities and the height at each corner (4, 5, and 6) is a measure of the  $P'$  value of the individual solvents. For samples of low and medium polarities the regular portion of the prism is used. In any triangle congruent to the base, all solvent mixtures are equi-elutotropic, meaning that the average  $R_F$  values for the sample components obtained with those mixtures will be about the same. In the third step, the stronger solvents are reduced by mixing them with a certain amount of hexane ( $P' = 0$ ) to arrive at the strength of the weakest solvent (7 and 8). For samples of very low polarity the strength of all three solvents may need to be reduced. In the fourth step, selectivity of the mobile phase system is varied to yield satisfactory resolution by changing the proportions of the adjusted 'corner' solvent, beginning with the center point and then moving to points close to the corners. For very polar samples optimization can be performed in the irregular top portion of the prism. In this region, usually only small changes are made in mobile phase

composition because they will also affect the average  $R_F$  value of the sample. If during the first step the solvent strength of the neat solvents is not sufficient to yield  $R_F$  values between 0.2 and 0.8, modifiers such as acids, bases, or water can be used in small proportions to deactivate the stationary phase. The pedestal of the prism represents these modifiers. If no satisfactory separation is obtained during this optimization process a new stationary phase or different solvents have to be chosen. For separations in RP systems the PRISMA model can also be employed. Instead of the  $P'$  value the  $S_T$  value is used and solvent strength is adjusted with water ( $S_T = 0$ ; see Table 3).

There are also other trial and error approaches, the simplest of which is the so-called spot test. The sample is applied as several spots on a TLC plate. Then specified volumes of different solvents are applied to the centers of the spotted samples. The resulting circular chromatograms can give preliminary information about solvent strength and selectivity required for separation of the sample. With modern instruments for sample application this test can be automated. However, actual optimization of the mobile phase must still be performed in a suitable chromatographic chamber.

CAMAG has proposed a practical scheme (Figure 4) for guidance during method development, which is derived from the PRISMA model but omits any

**Figure 4** CAMAG optimization scheme. For details see text. Note: The solvents selected in the scheme serve as examples and may be different for other separation problems.

calculation. Method development can be performed in saturated, unsaturated, or sandwich chambers. Initially, silica gel is selected as the stationary phase. At level 1 a set of 8–12 neat solvents is evaluated. Looking at the  $R_F$  values of the sample in the chromatograms three results are possible. In case (A),  $R_F$  values are between 0.2 and 0.8. These solvents are considered further in level 3. In case (B),  $R_F$  values are below 0.2. In case (C),  $R_F$  values are above 0.8. These solvents are taken to level 2, where either adding a small proportion of polar modifier such as water, acid, or base increases their strength, or the addition of hexane reduces it. On level 3, two solvents of suitable selectivity from level 1 (case A) and/or level 2 are combined in order to achieve improved separation. At this point small portions of acid, base, or water can be added to reduce tailing or improve the shape of the separated zones. If no improvement results two other solvents are combined. In level 4, the proportions of the selected solvents are slightly changed to optimize the result. If no satisfactory result is obtained during the process, another stationary phase has to be used. The approach works similarly and equally well for polar bonded phases. On reversed phases water is used to adjust solvent strength.

According to Nyiredy mobile phases for forced flow separations such as OPLC can also be selected

and optimized using the PRISMA model. In this process also one solvent is usually chosen, in which the sample does not migrate. This solvent can be used in a prerun to eliminate the so-called front of total wetness caused by undissolved gasses in the sealed layer.

For separations using the AMD technique not only solvent strength and selectivity can be varied but also the type of the gradient. Development of a method begins with a standard gradient from a strong solvent such as methanol, acetonitrile, or acetone over a medium polar base solvent such as dichloromethane, chloroform, or an ether to a nonpolar solvent like hexane. Fifteen to twenty developments of increasing distance typically reach 60 mm for the last step. Because the solvent composition at each point of the chromatogram is known the results can easily be optimized. The  $R_F$  values of the separated compounds are lowered by eliminating the steps containing large portions of polar solvent or by making the gradient steeper.  $R_F$  values are increased by eliminating the steps containing hexane, making the gradient less steep, or for very polar samples adding polar modifiers such as water, acid, or base in order to deactivate the stationary phase. Distances between separated zones are affected by changing the slope of the gradient. Exchanging the base solvent modifies selectivity of the separation.

## Optimizing the Detection

Throughout the entire method development process detection is an important step, particularly if samples of unknown composition are to be analyzed. To ensure that all noncolored sample components are detected in a qualitative analysis, the developed plate, which typically contains a so-called fluorescence indicator, is evaluated visually under ultraviolet (UV) at 254 nm. Substances absorbing this wavelength are seen as dark zones on fluorescing background. Evaluation under UV 366 nm detects all components, which are excited by that wavelength to fluoresce. Densitometric evaluation of the chromatogram at multiple wavelengths will detect all substances, which absorb between 190 and 800 nm. Substances without chromophors may be rendered detectable by employing various derivatizing agents. During the selection/optimization of the mobile phase universal reagents are often used for visualization. Examples include mixtures of sulfuric acid and anisaldehyde in methanol, copper(II) sulfate, and phosphoric acid in water, or phosphomolybdic acid. If the sample components are known also specific derivatization can be used to visualize the chromatogram. The visual impression often gives additional information about the quality of separation and the homogeneity of results across the plate.

When the separation is satisfactory the detection step has to be optimized. For densitometric evaluation in absorbance mode without derivatization this optimization includes the selection of the proper scanning wavelength based on spectral or multi-wavelength evaluation and choice of mechanical parameters such as scanning speed and slit dimension. For fluorescence measurements also the excitation wavelength and an appropriate cutoff filter are selected. If detection includes a derivatization step additional parameters must be optimized for reproducible results. Derivatization by immersing the plate into the reagent is a reproducible process. Parameters for optimization are reagent concentration, type of the solvent, and immersion time. Usually derivatization is completed by a heating step, for which temperature and duration have to be selected. In many cases the intensity and color of zones changes with temperature and time. Also, the fluorescence of separated substances or their derivatives is usually not constant over time. It goes through a maximum at some point and then decreases, but it can be stabilized or enhanced by covering the plate with viscous liquids such as paraffin or poly(ethylene glycol) by spraying or dipping. This prevents the excited sample molecules from relaxation and eliminates fluorescence quenching by oxygen.

When developing a quantitative TLC method also the amounts of the separated sample components have to be adjusted. It is desirable to work within a linear range of the corresponding calibration curve. Limits of detection (LOD) and quantitation (LOQ) have to be established for each component. These limits and the working range of the method determine the concentration at which the sample has to be prepared and the volume that has to be applied onto the plate.

## Method Validation

Prior to its use a method has to be validated. Validation is the formal proof that the method is suitable for the intended purpose. This requires that all steps and parameters of the method have been clearly specified in a written method description, any necessary equipment was qualified, and acceptance criteria for each validation point have been agreed upon. For quantitative methods the International Conference on Harmonization (ICH) has issued specific guidelines for setting up a validation protocol and for parameters that have to be validated for different applications. These include specificity, accuracy, precision, LOD, LOQ, linearity, and range as well as robustness. The only required validation parameter for qualitative methods is specificity.

For both qualitative and quantitative TLC methods it is useful to perform certain prevalidation experiments. This can be done during method development. Because TLC is an offline process and the TLC plate is an open system, which can be affected by various environmental factors, it is necessary to establish the stability of the analyte in solution, on the plate and during chromatography in order to avoid any artifacts. Furthermore, the stability of the mobile phase must be ensured. Stability during chromatography is investigated by a two-dimensional experiment. The sample is applied in the lower left corner of the TLC plate. After development the plate is dried, turned 90° to the left, and developed with fresh mobile phase according to the specification of the method. The sample is stable during chromatography if after the second development all sample components are on the diagonal connecting the application position with the intersection of the mobile phase fronts (Figure 5).

Because the TLC plate is used only once, intermediate precision (reproducibility of the result from plate to plate) is particularly important for methods intended for routine use. To maximize precision the method must be robust. During validation or during method development the effects of the following

**Figure 5** Evaluation of stability of the analyte in the chromatographic system by two-dimensional chromatography. Development in the first direction separates the mixture into its components. For each stable component the second development gives the same  $R_f$  value as the first development. Any substance that is located off the diagonal is formed during chromatography. For further details see text.

parameters are typically assessed: relative humidity, performance of plates from different batches and manufacturers, developing distance, times for chamber saturation, heating times and temperature during derivatization, and waiting times between the individual TLC steps.

## Introduction

Thin-layer chromatography (TLC) is considered a simple technique and it can be successfully performed without sophisticated instrumentation. However, the quality and reproducibility of results can be significantly improved if instrumentation is utilized. To unlock the full potential of modern high-performance TLC (HPTLC) and to automate its individual steps, state-of-the-art equipment is a necessity. This article describes modern instrumentation for all steps of the TLC process in its functionality.

## Sample Application

Devices for application have to ensure proper positioning of the sample on the TLC plate and precise

dosage of specified sample volumes. Furthermore, any damage to the layer must be avoided. Modern instruments support positioning of samples in  $x$ - and  $y$ -directions either in predefined or freely selectable increments. While manual devices generally utilize a ruler, automated sample applicators include software-controlled mechanics to position the sample reproducibly. For manual sample dosage, disposable fixed volume capillaries, graduated micropipettes, or microsyringes are used. Automated instruments use motor-driven syringes. There are two principal ways of transferring the sample onto the layer, contact spotting and spray-on application. During contact spotting the sample is transferred into the layer by capillary action, when the capillary or needle touches the surface. The duration of contact and the dispensed sample volume determine the size of the applied spot. If the sample is dissolved in a strong (polar) solvent and large volumes are applied, circular chromatography will take place during application resulting in poorly separated and distorted

**Figure 5** Evaluation of stability of the analyte in the chromatographic system by two-dimensional chromatography. Development in the first direction separates the mixture into its components. ## Introduction

Thin-layer chromatography (TLC) is considered a simple technique and it can be successfully performed without sophisticated instrumentation. However, the quality and reproducibility of results can be significantly improved if instrumentation is utilized. To unlock the full potential of modern high-performance TLC (HPTLC) and to automate its individual steps, state-of-the-art equipment is a necessity. This article describes modern instrumentation for all steps of the TLC process in its functionality.

## Sample Application

Devices for application have to ensure proper positioning of the sample on the TLC plate and precise

dosage of specified sample volumes. Furthermore, any damage to the layer must be avoided. Modern instruments support positioning of samples in  $x$ - and  $y$ -directions either in predefined or freely selectable increments. While manual devices generally utilize a ruler, automated sample applicators include software-controlled mechanics to position the sample reproducibly. For manual sample dosage, disposable fixed volume capillaries, graduated micropipettes, or microsyringes are used. Automated instruments use motor-driven syringes. There are two principal ways of transferring the sample onto the layer, contact spotting and spray-on application. During contact spotting the sample is transferred into the layer by capillary action, when the capillary or needle touches the surface. The duration of contact and the dispensed sample volume determine the size of the applied spot. If the sample is dissolved in a strong (polar) solvent and large volumes are applied, circular chromatography will take place during application resulting in poorly separated and distorted

**Figure 1** Nanomat 4 (photograph courtesy of CAMAG.)

chromatogram zones. This has great consequences for the achievable resolution during development of the plate. The spray-on technique overcomes these problems. The sample is atomized with the help of compressed air or inert gas when it leaves the tip of the applicator's syringe. This way a sharply focused starting zone can be achieved. If the spray nozzle is moved relative to the TLC plate during application the sample is sprayed on as a narrow band. By adjusting the dosage speed, wetting of the stationary phase during application can be avoided, thus eliminating any undesired chromatography.

The Nanomat (CAMAG, Switzerland) (Figure 1) is a simple instrument for manual sample application as spots. Using capillaries, 0.5, 1, 2, or 5  $\mu$ l volumes can be applied as spots with distance in multiples of 5 mm. The application position is also selectable in the y-direction. With a capillary holder a disposable capillary is obtained from a dispenser and filled by immersing the tip into the sample. After placing the holder against the applicator head, where it is held by magnetic force, the sample is applied by gently pushing down the applicator head until the capillary makes contact with the layer.

The TLS100 (Desaga, Germany) is designed for automated spot application from a motor-driven syringe. The instrument can be programmed via keypad to apply up to 30 samples and four standards on up to six TLC/HPTLC plates of 20  $\times$  10 cm. The instrument can also generate bands by dividing the specified sample volume into small spots applied side by side. A similar device is the TLC AutoSpotter (Analtech, USA), which can be fitted with up to 18 syringes for simultaneous spot application of multiple samples.

The first semiautomatic instrument utilizing all advantages of the spray-on technique was the (Linomat 5) (Figure 2). Today's latest model is software controlled. Only the y-position of the application is set manually and the user loads the sample into the

**Figure 2** Linomat 5 (photograph courtesy of CAMAG).

syringe. Sample size is adjustable from 100 nl to 2 ml. The selectable band length is 0–195 mm length.

A fully automatic, software-controlled application device is the AS30 (Desaga, Germany). When combined with a regular autosampler up to 30 samples can be applied as spots or bands. The ATS4 (CAMAG, Switzerland) is the most sophisticated and versatile system for sample application. Fully software-controlled, up to 66 samples from vials or 96 samples from well plates can be applied. Volumes and any x- or y-position of the TLC plate are freely selectable for either contact spotting or spray-on application. Large sample volumes containing a high percentage of matrix can also be applied as rectangles for clean-up by predevelopment.

## Chromatogram Development

Although TLC plates can generally be developed in three geometrical modes, linear, circular (radial), and anticircular, today only linear development is of practical relevance. Due to the presence of a gas phase in addition to stationary and mobile phases, TLC differs from all other chromatographic techniques. For ensuring reproducible chromatographic results this gas phase must be carefully controlled because it affects the separation significantly. Chamber form and chamber saturation are playing a dominant role in this regard. Even though there are generally neither good nor bad chambers it must be

expected that all chambers will give somewhat different results.

### Conventional Developing Chambers

The traditional flat-bottom chamber is readily available and comes in many shapes (cylindrical or rectangular) and sizes to fit almost any plate format. The typical 'chromatographic tank' is made of glass and has a rectangular base. The chamber can easily be saturated when one or more walls are lined with filter paper, which is wetted with developing solvent. The flat-bottom chamber has two major disadvantages, the high solvent consumption and the difficulty of securely placing the TLC plate into it. Nevertheless, flat-bottom chambers are widely used.

Twin Trough Chambers (CAMAG, Switzerland) (Figure 3) are also very popular and represent an economic and very flexible alternative. Available in sizes to fit  $10 \times 10$  cm,  $20 \times 10$  cm, and  $20 \times 20$  cm plates these chambers require very little solvent. For example, only 5 ml of developing solvent are needed to develop a  $10 \times 10$  cm HPTLC plate in unsaturated mode. In this mode only the front trough is charged with solvent and development is started immediately. In the saturated mode both troughs are charged and the rear trough is fitted with filter paper, which was wetted with solvent. In a Twin Trough Chamber the TLC plate can be easily preconditioned. While positioned in the empty front trough, having the stationary phase face the inside of the chamber, the plate is exposed to vapor from a conditioning solvent such as acid, base, solution affecting humidity, or developing solvent. Following the conditioning step the mobile phase is carefully introduced into the front trough and chromatography is started.

**Figure 3** Twin trough chambers (photograph courtesy of CAMAG).

### Special Chambers

Several special chambers are on the market, which allow development of TLC plates in a horizontal mode. The Horizontal Separation Chamber (Desaga, Germany) is available for  $5 \times 5$  cm and  $10 \times 10$  cm plates. The Horizontal Developing Chamber (CAMAG, Switzerland) (HDC) (Figure 4) offers additional flexibility. Available in two formats, for  $10 \times 10$  or  $20 \times 10$  cm HPTLC plates, the device allows simultaneous development from opposite edges of a plate. This way up to 72 samples applied as spots are analyzed in parallel. Both horizontal chambers can be operated in saturated, unsaturated, and sandwich modes. For the latter a counter-plate is put in place. The central compartment of the chamber can be charged with a suitable liquid for preconditioning a plate or operation in saturated mode.

A useful tool for method development and optimization of chromatographic parameters is the VARIO Chamber (CAMAG, Switzerland). On  $10 \times 10$  cm HPTLC plates, which have been previously scored to form six parallel tracks, up to six different solvents or six different conditions can be investigated. The chamber can also be operated in saturated, unsaturated, or sandwich mode, thus enabling convenient transfer of the optimized separation conditions to a HDC.

The CycloGraph system (Analtech, USA) (Figure 5) is a centrifugally accelerated device for performing preparative chromatographic separations. The device spins a layer of adsorbent material coated as a flat ring on a glass backing. A solvent pump is used to apply the sample and mobile phase to the center of the spinning adsorbent ring. The centrifugal force accelerates the flow of the mobile phase through the adsorbent, separating the sample components as circular bands. The mobile phase elutes continuously into a collection channel inside the body of the instrument.

**Figure 4** Horizontal developing chamber (photograph courtesy of CAMAG.)

**Figure 5** CycloGraph (photograph courtesy of Analtech, used by permission).

Other special devices, which are of historical interest, include a special chamber for short bed continuous development. In this technique, the plate extends through a slit out of the actual chamber allowing the developing solvent to evaporate. Separation of very similar compounds can thus be achieved at low  $R_f$  values. The U-chamber according to Kaiser was a special device for circular and anticircular HPTLC.

### Automatic Chambers

The primary purpose of automatic chambers is ensuring highest possible reproducibility of the chromatographic result in routine analysis. Therefore, the instrument controls most parameters of the developing step. The Automatic Developing Chamber (CAMAG, Switzerland) (ADC) is designed for classical one-step isocratic development in tank or sandwich configuration. Through a charge-coupled device (CCD) element, the ADC controls the migration distance of the mobile phase. Prior to start of development the TLC plate can be preconditioned through the gas phase. When development is complete the systems can dry the plate automatically. A very similar instrument is the TLC-MAT (Desaga, Germany).

### Automated Multiple Development

A technique that can achieve the maximum attainable resolution in TLC on a given separation distance without forced flow is automated multiple development (AMD). This step-gradient technique was developed by Burger. With respect to peak capacity the technique can be compared to HPLC, but it still maintains all benefits of planar chromatography. The heart of the instrument is a specially designed vacuum-tight chamber. Following sample application

the HPTLC plate of  $20 \times 10$  cm is precisely positioned in the chamber. The mobile phase for each development is prepared automatically by mixing appropriate portions of solvent from up to five different reservoirs. The mobile phase is then introduced into the chamber. Chromatography begins and is monitored by a CCD element, which stops the run if the selected developing distance has been reached. Vacuum from a pump is connected, remaining solvent withdrawn from the chamber, and the plate completely dried. While vacuum is released the plate can be preconditioned via the gas phase, leaving the system ready for the next development step. An AMD gradient always starts over a short distance (2–3 mm) with a mobile phase of high elution power to ensure that the sample, which has been applied as a narrow band, is completely removed from the application position and at the same time further concentrated. Successive runs will be performed with decreasing solvent strength but increasing developing distance. Development of a method for an unknown sample typically begins with a so-called universal or scouting gradient which over 20 to 25 steps and 60 mm developing distance changes from methanol over dichloromethane to hexane. Separation of samples is primarily based on polarity. However, by changing the selectivity of the mobile phase components resolution can easily be changed. Changing the slope of the gradient will affect the distance between zones. One of the advantages of ADM is that desired changes in a given chromatogram can be predictably performed. AMD solvents must be especially pure in order to avoid accumulation of impurities during multiple developments. Because drying of the plate between the individual steps is performed by vacuum AMD solvents must have a sufficient volatility. On the other hand, samples separated by AMD must not be volatile. The AMD 2 (CAMAG, Switzerland) instrument (see scheme **Figure 6**) is fully computer controlled and integrated in a GMP-compliant software. All gradient parameters are conveniently programmed in a spreadsheet. AMD is a highly reproducible but somewhat time-consuming technique. Typical fields of application include analysis of pesticides, lipids, and screening for biological activity.

### Visualization, Detection, and Documentation

The possibility of generating a visual image of the chromatographic result is one of the principal advantages of TCL. It is a common practice to first 'look' at the result before the plate is subjected to further evaluation. Colored substances can be seen

**Figure 6** AMD 2 with a syringe (8) via the motorized valve (1) the selected portions of solvent are taken from the storage bottles (15) and delivered to the chamber (9). When the mobile phase has reached the programmed height on the plate (10) the chamber is drained into the waste bottle (16) and the plate is dried by vacuum from a pump (18). Vacuum is released through conditioning bottles (6, 7) allowing adjustments to the gas phase in the chamber. (photograph courtesy of CAMAG.)

**Figure 7** Instruments for visualization of plates. (A) UV cabinet, (B) documentation system with digital camera, and (C) documentation system with video camera (photograph courtesy of CAMAG and Desaga).

directly. Substances that can be excited to fluoresce by ultraviolet (UV) light can be visualized under a lamp emitting UV at 366 nm. Quenching of a so-called UV indicator can visualize substances that absorb UV light of 254 nm. The UV indicator is excited by UV at 254 nm and emits either green or blue light. Quenching zones of UV absorbing substances are seen as dark zones on fluorescing background when the plate is viewed under the UV lamp. Several UV lamps (Figure 7A) and viewing cabinets are on the market, combining UV 254 nm and UV 366 nm light in reflectance as well as white light in transmission, reflectance, and mixed illumination modes. Substances that are not seen in any of these modes have to be derivatized or otherwise visualized for evaluation and documentation.

For the purpose of documentation modern viewing cabinets such as the Reprostar3 (CAMAG, Switzerland), the VD30 (Desaga, Germany), or the ChromaDoc-it (Analtech, USA) can be fitted with a video or digital camera (Figures 7B and 7C). This software-controlled setup allows instant, reliable, and reproducible capture of electronic images, which are durable, can be conveniently annotated and exchanged, and allow quantitative densitometric evaluation. Documentation in white light is also possible with flatbed scanners. The traditional way of documenting the chromatographic result by photography cannot compete with the advantages offered by electronic systems.

### Derivatization

Prechromatographic derivatization is a useful tool to change the chromatographic behavior of the sample or some of its components in order to increase their stability, improve separation, or reduce matrix effects. It is either performed as part of sample preparation or following sample application *in situ* on the TLC plate. Postchromatographic derivatization is a necessary step in TLC if a sample component is otherwise undetectable and if selectivity or sensitivity of detection can be improved.

**Instruments** From a practical point of view, the principal requirements for derivatization are homogeneity of reagent transfer across the TLC plate and repeatability of the results from plate to plate. Ideally, the amount of reagent involved in derivatization should be controlled as well as the time and temperature of

any subsequent heating step required for completion of the reaction. For qualitative investigations these requirements are typically less stringent.

A very uniform derivatization is possible (yet not generally applicable) if the reagent is transferred via the gas phase using a twin trough chamber or a special conditioning chamber. In the case of a twin trough chamber the developed and solvent-free TLC plate is positioned in one trough, while the other trough is either charged with the reagent (for example, iodine) or with a mixture of chemicals generating the reagent *in situ* (for example, permanganate and hydrochloric acid to generate chlorine).

The majority of reagents are used in a solution the TLC plate can either be sprayed with or dipped into. Spraying uses comparatively small volumes of reagent and is very flexible. It is also often the method of choice, if a sequence of reagents has to be applied. The principal disadvantage is the difficulty of ensuring homogeneity and reproducibility. Another problem is the generation of fumes and aerosols, which for safety require spraying to be performed in a hood or special spray cabinet. There are many different reagent sprayers available that utilize the atomizer principle (Figure 8A). They are operated manually with a rubber bulb pump, compressed air, or electropneumatically. The Chromajet (Desaga, Germany) (Figure 8B) is a sophisticated fully automatic spraying device that can solve all problems associated with manual spraying. The exact amount of reagent applied to each of up to 30 defined areas of the plate can be specified. A built-in exhaust fan removes the fumes generated.

Derivatization by immersion offers several advantages. Controlling the concentration of the reagent solution and the immersion time allows increased reproducibility. The coverage of the plate is always uniform and the consumption of reagent per plate is low if the reagent is used repeatedly. Generally, solutions for immersion are less concentrated (only ~20%)

than those for spraying. No fumes are generated and the exposure of the operator to chemicals is limited. The principal disadvantage of immersion is the potential for diffusion of separated zones and even elution from the plate during immersion, if the sample components are readily soluble in the solvent of the reagent. A typical immersion device is shown in Figure 9. It allows selection of immersion speed and immersion time. The plate is smoothly lowered into the reagent thus eliminating any 'tide marks' typically encountered in manual dipping.

In most cases the derivatization reaction is initiated and/or completed by a heating step, which can be performed in a conventional oven or on a plate heater. For optimum reproducibility modern plate heaters ensure homogenous temperature across their surface and allow precise adjustment over a wide temperature range, typically up to 200°C.

**Reagents** Chemical derivatizing agents are generally grouped in specific and nonspecific or universal reagents. The latter include acids such as hydrochloric, phosphoric, and sulfuric, which can char many organic compounds at elevated temperature to yield colored and finally dark brown products. Addition of aldehydes such as anisaldehyde or vanillin to the reagent leads to characteristically colored zones for many natural products. Other universal reagents include antimony(III) or (V) chloride and phosphomolybdic acid.

**Figure 9** Immersion device (photograph courtesy of CAMAG).

**Table 1** Common reagents for identification of functional groups

Functional group	Reagent	Comments
Acetylene compounds	Dicobalt octacarbonyl	Formation of colored compounds
Aldehydes	2,4-Dinitrophenylhydrazine	Formation of colored hydrazones and osazones
Alcohols, polyols, sugars	Lead(IV) acetate-dichlorofluorescein	Cleavage of vicinal diols
Amines (primary), amino acids	Ninhydrin	Formation of reddish-bluish compounds
Amines (primary and secondary)	7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-chloride)	Formation of fluorescent derivatives
Amines (capable of coupling)	Fast blue salt B and BB, fast black salt K, diazosulfanilic acid, diazosulfanilamide, 4-nitroaniline	Formation of azo dyes
Carboxyl groups	2,6-Dichlorophenolindophenol	Organic acids and undissociated acids become blue and reductants colorless
Ketones	2,4-Dinitrophenylhydrazine	Formation of colored hydrazones and osazones
Peroxides	Potassium iodide with starch	Formation of iodine from iodide, which forms blue complex with starch
Phenols, thiols	7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-chloride)	Formation of fluorescent derivatives

A list of reagents specific for certain functional groups is given in **Table 1**.

### Detection of Bioactivity

By focusing on their microbiological or biological and physiological activity a number of compounds can be detected. For bioautography, enzymes or test organisms such as spores, yeast cells, cell organelles, or bacteria in a nutrient medium can be directly transferred onto the plate by dipping. Biological activity is detected either immediately or following incubation typically involving enzymatic reactions or assessment of growth, respectively, their inhibition, linked to certain color changes. A commercial kit for detection of antibiotic activity based on growth inhibition of *Bacillus subtilis* is available from E. Merck. The developed TLC plate is dried and then immersed in a suspension of bacteria. Following incubation the plate is sprayed with MTT tetrazolium salt reagent (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide). Antibiotics inhibiting the growth of the bacteria appear as bright zones on colored background. Another kit, supplied by ChromaDex, is based on instant detection of effects on the chemiluminescence of *Vibrio fischeri*. Following development the TLC plate is immersed in the bacteria solution and immediately evaluated in a dark room using a very sensitive digital camera. Active compounds can either further excite or inhibit the luminescence of the bacteria seen as brighter or darker zones on a weakly glowing background.

### Detection of Radioactivity

Radioactively labeled compounds can be detected by autoradiography. Traditionally, the developed plate is

brought in contact with a special X-ray film suitable for the investigated isotopes. After development this film serves as an image of the plate, which can be densitometrically evaluated. Filmless autoradiography can be performed with so-called storage phosphor screens. The central element of this technology is a reusable phosphor screen, which is sensitive to ionizing radiation. In contact with the TLC plate containing labeled compounds an image is imprinted into the screen, which can be read out during a scanning step. Prior to a subsequent use of the screen the image is erased by exposure to visible light. Most recent approaches are based on electronic autoradiography directly measuring the radioactivity on the TLC plate with a position sensitive multiwire proportional counter chamber (Charpak, Nobel prize for physics 1992), or a proportional gas flow counter chamber. Modern instruments such as RITA or GITA (Raytest, Germany) allow real-time evaluation of chromatograms.

### Densitometry

For qualitative and quantitative evaluation of chromatograms in TLC, densitometry is the preferred technique. In general, a signal obtained from a position of the TLC plate that contains the sample component is compared to the signal of the plate without sample, which serves as baseline. The signal is displayed as a function of position thus generating an analog curve of the chromatogram. Following integration and peak detection the chromatogram can be evaluated quantitatively based on peak area and/or height of the investigated compound against a calibration curve generated from peak data of standards chromatographed on the same plate.

### Scanning Densitometry

In scanning densitometry a beam of light of selectable dimension and wavelength is moved across the plate following the individual tracks in direction of chromatography. In absorbance mode a photomultiplier is used to measure the amount of light, which goes either through the TLC plate (transmission mode) or is diffusely reflected from the surface of the plate (reflectance mode). Transmission measurements are of limited applicability because irregularities of the layer significantly affect the results and only white light can be used. For scanning in reflectance mode the spectral range from 190 to 800 nm can be utilized. Most frequently the absorbance of a substance is measured. Although the response of the photomultiplier is linear to the amount of received light the dependence of the signal on the amount of substance is essentially nonlinear. This phenomenon is caused by the fact that the sample is located not only on the surface of the stationary phase but also in deeper layers and these layers do not contribute to the signal to the same degree. This phenomenon is best described by the Kubelka–Munk equation.

The second type of measurement is that of fluorescence. It can be applied to substances that are excited by UV light. Prior to reaching the photomultiplier (PM) the UV light used for excitation is quantitatively absorbed by a cut-off filter so that no reflected light is measured. The fluorescent light emitted by the sample is able to pass the filter and reach the PM.

Modern densitometers such as the CD60 (Desaga, Germany), the CS9000 series (Shimadzu, Japan), and the TLC Scanner 3 (CAMAG, Switzerland) are single-beam, single-wavelength instruments controlled by powerful software managing all mechanical

functions and the evaluation of scan data. Figure 10 illustrates the principal design of such instruments using the TLC Scanner 3 as example. The densitometer consists of a compartment for exact positioning of the plate on a stage, electronic parts, and the optical system. Three lamps, a deuterium lamp covering the UV region of the spectral range, a mercury vapor lamp providing a spectrum of several lines of high intensity, and a tungsten lamp producing white light are available to cover the UV and visible range of the spectrum. After passing a lens system the emitted light reaches the monochromator, a holographic grating for selection of the scanning wavelength ( $\sim 20$  nm bandwidth). Through a revolving disk with fixed apertures the appropriate slit dimension is chosen. Finally, a beam splitter directs a part of the light beam to a reference photomultiplier reducing fluctuation and effects of lamp aging. The other part of the beam reaches the plate for measurement.

Another feature of modern densitometers is the option of recording spectra. For that purpose the light beam is positioned on the zone, of which the spectrum is to be obtained. Then the wavelength of the light is changed to cover the selected spectral range. After applying corrections for the lamp and the background the resulting spectrum can be used for identification of the separated substance.

### Video Densitometry

Video densitometry is usually performed on electronic images of the visualized chromatogram. Software such as VideoScan (CAMAG, Switzerland) and ProResult (Desaga, Germany) evaluates the pixels of each line of the image, which are within the user-selected tracks, according to their intensity on a 256 level gray scale. The resulting analog curve can

**Figure 10** Scheme of the light pass of the TLC Scanner 3 (photograph courtesy of CAMAG).

be used for quantitation by comparison to curves generated with calibration standards. Advantages of video densitometry are simplicity and speed. The major disadvantage compared to scanning densitometry is the absence of spectral selectivity. Only substances that can be visualized are accessible for the technique.

## TLC Software

As an offline technique the TLC process consists of several individual steps. Traditionally, instruments for each step are controlled by separate more or less sophisticated software. winCATS-Planar Chromatography Manager (CAMAG, Switzerland) is the first integrated software that can communicate with all instruments involved in the TLC process. A winCATS method file can include information about the stationary phase, samples and their components, standards and their preparation, application parameters, prechromatographic derivatization, development conditions, postchromatographic derivatization, all parameters of densitometric and spectral evaluation, and details of electronic documentation using a

digital or video camera. While the first step of a method is executed an analysis file including an analysis log is generated. The user is prompted to initiate the next step after the TLC plate has been manually transferred into the next instrument. The software is fully compliant with cGMP/cGLP and ready for use in an environment compliant to US CFR 21 rule 11.

## Introduction

Tin is a group IV element of atomic number 50 and atomic weight 118.71. Of all the elements it has the largest number of stable isotopes (10) with relative atomic masses ranging from 112 to 124. Tin normally exists in the oxidation states of +2 or +4, with tin(IV) being the more stable.

The toxicity of an element such as tin is highly dependent upon its chemical form. It is of relatively low toxicity in its inorganic form whereas the tri-substituted organotin forms of  $R_3SnX$  (where R is an aryl or alkyl group) are of very high toxicity. The ability to determine the levels of each species

of tin is thus highly important in determining the toxic impact on our environment. Government regulations have come into existence over the last decade requiring the monitoring of different forms of tin, in particular as specific organotins. A range of methods has been applied to organotin speciation analysis and some very elegant hyphenated techniques such as gas chromatography inductively coupled plasma mass spectrometry (GC-ICP-MS) have been employed.

## Total Tin Determination

Currently, many routine testing laboratories still determine only total tin concentrations in samples. This analysis typically involves complete digestion of the sample in a mixed acid media or alkali fusion of the material. Alkali fusion with compounds such as

be used for quantitation by comparison to curves generated with calibration standards. Advantages of video densitometry are simplicity and speed. The major disadvantage compared to scanning densitometry is the absence of spectral selectivity. Only substances that can be visualized are accessible for the technique.

## TIN

**L G Mackay**, National Analytical Reference Laboratory, Pymble, NSW, Australia

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

Tin is a group IV element of atomic number 50 and atomic weight 118.71. Of all the elements it has the largest number of stable isotopes (10) with relative atomic masses ranging from 112 to 124. Tin normally exists in the oxidation states of +2 or +4, with tin(IV) being the more stable.

The toxicity of an element such as tin is highly dependent upon its chemical form. It is of relatively low toxicity in its inorganic form whereas the tri-substituted organotin forms of  $R_3SnX$  (where R is an aryl or alkyl group) are of very high toxicity. The ability to determine the levels of each species

of tin is thus highly important in determining the toxic impact on our environment. Government regulations have come into existence over the last decade requiring the monitoring of different forms of tin, in particular as specific organotins. A range of methods has been applied to organotin speciation analysis and some very elegant hyphenated techniques such as gas chromatography inductively coupled plasma mass spectrometry (GC-ICP-MS) have been employed.

## Total Tin Determination

Currently, many routine testing laboratories still determine only total tin concentrations in samples. This analysis typically involves complete digestion of the sample in a mixed acid media or alkali fusion of the material. Alkali fusion with compounds such as

$\text{LiBO}_2$  can be carried out in a platinum crucible at  $1000^\circ\text{C}$ . Acid digestion typically involves acid mixtures such as concentrated nitric and hydrochloric acid heated to temperatures of  $100^\circ\text{C}$  or more. The aim of the digestion in this case is to completely break down the matrix. Total tin analysis is routinely carried out using atomic absorption spectrometry (AAS) and inductively coupled plasma (ICP) coupled with atomic emission spectrometry (AES) or with mass spectrometry (MS). Hydride generation is commonly used to reduce detection limits. This technique involves the addition of a reductant such as sodium borohydride to form tin hydride. Hydride generation has been used commonly with ICP-AES, ICP-MS, and AAS. Other techniques employed for total tin determination are instrumental neutron activation and X-ray fluorescence spectrometry.

## Organotin Compounds

Tin forms a wide range of organic compounds as a result of the formation of covalent bonds to  $\text{Sn(IV)}$ . These compounds are commonly referred to as organotins. Organotins have a wide range of industrial applications and hence they are now widely found in the environment. Analytical methods have been developed to carry out tin speciation to determine the different forms of organotins present in the environment as opposed to the determination of total tin levels. Inorganic tin is considered to be harmless, however, trisubstituted organotins have high toxicity and environmental guidelines now are internationally starting to include specific requirements for maximum allowed levels of triorganotins.

Two of the major organotin environmental contaminants are tributyltin and triphenyltin. Both are used as antifouling agents on marine vessels where they are applied to reduce the buildup of organisms on ships hulls. Triphenyltin has also been used as a fungicide and pesticide. Tricyclohexyltin is less common but is used as an acaricide to kill mites and ticks. Once these trisubstituted species are present in the environment, they degrade to less substituted species following a path of loss of the organic groups via the di- and monosubstituted species down to inorganic tin finally. **Figure 1** shows the tri-, di-, and monosubstituted forms for the butyltin chloride species.

Unfortunately this degradation process is slow, particularly once the trisubstituted species are bound to sediments in the environment. Dibutyltin and monobutyltin, the decomposition products of tributyltin, are also used industrially as stabilizers in chlorinated polymers such as PVC and hence their contamination has been found in a wide range of

**Figure 1** Structures of tri-, di-, and monobutyltin chloride species, three commonly determined environmental contaminants.

different matrices. Octyltin species have also been reported in environmental samples. Methylated tin species have been observed, which can form as a result of the methylation of inorganic tin in the environment. The tetrasubstituted species such as tetrabutyltin are of low toxicity and are mainly used as synthetic precursors for other organotins. They do have a delayed toxic effect as a result of their degradation to less substituted species.

One of the major environmental problems with organotins is that they accumulate in sediments, which are the ultimate environmental sinks for contaminants such as this. Many aquatic organisms, such as oysters and mussels, suffer from buildup of toxic levels of these contaminants because they are filter feeders and thus bioaccumulate these contaminants as a result of this. Significant malformation and growth retardation has been observed in aquatic organisms following exposure to organotin species and compounds such as tributyltin are suspected endocrine disruptors.

The use of tributyltin, the major environmental contaminant, as a biocide is now strictly regulated in most countries, however, its levels in waters and coastal sediments remain high enough to pose a significant toxicological risk. Many early analytical methods for organotins concentrated only on the trisubstituted species due to their high toxicity. However, as the demand to understand more about the biogeochemical pathways and degradation patterns of the trisubstituted species has grown, methods have been extended to include the less substituted species. Environmental monitoring now typically involves looking at the range of tri-, di-, and monosubstituted species present in sediments, water, and aquatic organisms. This range of testing enables authorities to obtain a true indication of the spread of contamination throughout the environment.

In the environment, organotins are associated with a range of different counterions, for example, they exist as chlorides, hydroxides, or oxides. Quantification of the levels of organotins concentrates on preserving the toxic organic component and measuring this species, irrespective of the type of counterion present. Organotin determination methods are

required to have an effective extraction technique followed by a separation technique coupled with a suitable detector. The various components of such methods are outlined in the following sections. Additional important factors such as sample storage, sample cleanup, and calibration techniques are also discussed.

## Extraction Techniques for Organotin Speciation

Traditional digestion techniques for total tin analysis are inappropriate for organotins as all species information is lost. Therefore, much more refined extraction techniques have to be developed. One of the major concerns in the extraction of organotins is the compromise between efficiently extracting the species while inducing minimal degradation of the specific individual compounds, which might result in distortion of the ratio of species present. The situation is made more complex by the fact that the polarity of the various species covers a wide range, with monosubstituted organotins having reasonably high polarity in comparison with their relatively nonpolar trisubstituted counterparts. To minimize this problem, chelating agents such as tropolone or diethyldithiocarbamate are sometimes employed which chelate with the organotins, particularly monobutyltin, forming less polar complexes which can be extracted with solvents suitable for the more highly substituted tin species.

The commonly used extraction techniques for organotins are mechanical shaking, ultrasonic extraction, microwave-assisted extraction, or pressurized fluid extraction. Simple mechanical shaking has been used by many testing laboratories, but this has been generally shown to be less effective than the latter three techniques, particularly with respect to recoveries for monosubstituted species. One of the advantages of shaking or ultrasonication is that they

have been observed to give lower levels of degradation. By contrast, microwave and pressurized fluid extraction techniques need to be more carefully optimized to avoid degradation but under the right conditions can provide high recoveries with minimal degradation.

It should be noted that it is difficult to find a universal extraction technique, which is applicable to all forms of the various tri-, di-, and monosubstituted organotins. Acids have generally been employed for the extraction of sediments. Where an inorganic acid such as HCl is used, concentrations above about  $1 \text{ mol l}^{-1}$  have been observed to cause degradation of organotins, and therefore their concentrations need to be limited. A combination of halogenated acid and organic solvent (with or without the addition of a chelating agent such as tropolone) has been used in many cases. Recently weaker acid systems such as aqueous acetic acid have been shown to be effective with the advent of extraction systems utilizing microwave or pressurized fluid conditions. For biota samples, basic and enzymic hydrolysis have been used to digest samples (Table 1).

### Mechanical Shaking and Ultrasonic Extraction

Mechanical shaking and ultrasonication of samples are traditional extraction techniques for organotins requiring limited specialized equipment. With appropriate solvents or chelating agents they can effectively extract a range of organotin species, although shaking often requires longer extraction times, typically several hours.

### Microwave Extraction

Microwave-assisted extraction has become one of the most widely applied techniques for organotins in sediments and biota. The important concept for effective speciation is the use of a low power microwave field (e.g. 50–100 W). Microwave digestion is commonly employed for total tin analysis where

**Table 1** Summary of a range of reported extraction procedures for a range of organotin species in environmental matrices

<i>Matrix</i>	<i>Extraction solvent</i>	<i>Species extracted/analyte</i>
Sediment	Hydrochloric acid followed by hexane	Tri-, di-, and monobutyltin
Sediment	Acetic acid followed by tropolone in toluene	Tri-, di-, and monobutyltin, tri-, di-, and monophenyltin, tri- and dicyclohexyltin, di- and monoethyltin
Sediment	Acetic acid and methanol	Tri-, di-, and monobutyltin, tri-, di-, and monophenyltin
Oyster	Hydrochloric acid followed by tropolone in hexane	Tri-, di-, and monobutyltin, tri-, di-, and monophenyltin
Mussel	Acetic acid and methanol	Tri-, di-, and monobutyltin
Fish and mussel	Aqueous tetramethylammonium hydroxide	Tri-, di-, and monobutyltin, tri-, di-, and monoethyltin

complete destruction of the matrix is desired, however, at low microwave powers organotin species can be leached without cleavage of the Sn–C bonds. Solvents such as glacial acetic acid, aqueous acetic acid, or methanolic acetic acid are most commonly used for sediments with extraction times using modern automated microwave systems of only around 5 min. Biota is often digested with tetramethylammonium hydroxide in a short 2–3 min extraction at low power.

### Pressurized Fluid Extraction

Pressurized fluid extraction using automated systems has become a highly popular extraction technique for organotins. The method allows the effective extraction of the species using short extraction times with minimal solvent. Typical conditions are 5–10 min extractions with temperatures  $\sim 100^{\circ}\text{C}$  and pressures  $\sim 2000$  psi. Simple solvent mixes such as methanolic acetic acid have been commonly employed with minimal degradation observed under these conditions.

### Solid Phase Microextraction

Solid phase microextraction (SPME) involves extraction onto a thin fiber and the technique has become more prevalent recently and additionally provides a preconcentration of analytes prior to analysis. The fibers used in the technique can be coated with a range of stationary phases and a non-polar phase such as polydimethylsiloxane (PDMS) is typically used for the extraction of derivatized organotin species. An equilibrium is established between the sample extract solution (or the headspace above the solution) and the stationary phase coating the fiber. The analytes are then typically desorbed from the fiber for analysis, for example, using thermal desorption during GC analysis. The technique allows rapid and solvent-free extraction of the analytes. Very good extraction has been achieved for water samples; however, the technique has been shown to be more variable with more complex matrices.

## Separation Techniques

For the effective analysis of organotin species, hyphenated analysis techniques are generally required involving separation of the individual species followed by an appropriate detection system. The two main chromatography techniques available for separation of these species are liquid chromatography (LC) and GC.

### Liquid Chromatography

Several forms of LC have been used for the separation of organotins. These techniques offer a simple, direct separation, which does not require derivatization of the species. The main disadvantages are the lower resolution available with LC and the limitations on detectors that can be coupled to LC for organotin analysis. Ultraviolet detection is not appropriate due to its very poor sensitivity for tin; however, fluorimetry has been successfully employed. The recent development of the two hyphenated techniques of LC–MS and LC–ICP–MS has provided two sensitive and selective detectors available for LC speciation.

The two main forms of LC, which have been applied to organotin analysis, are ion-exchange chromatography (using silica based cation-exchange columns) or reverse-phase chromatography (using C18 columns). In the former case, the monosubstituted organotins bind much more tightly than the di- and trisubstituted forms to the stationary phase, and hence mobile phase gradients, which vary the levels of complexing agents and pH, have been employed. Reverse-phase columns have become more widely used recently with mobile phases such as methanol/water/acetic acid employed with modifiers such as triethylamine. Under reverse-phase conditions, the various tin species can often be separated under isocratic conditions, which is more amenable to modern detection systems such as ICP–MS.

### Gas Chromatography

GC offers excellent chromatographic resolution and can be coupled to a range of appropriate detectors for organotin detection such as MS, ICP–MS, atomic emission (AED), AAS, and flame photometric detectors (FPD). The main problem with GC is the low volatility of all organotin species except in the tetraorganotin forms. This means that a derivatization step is required prior to GC analysis. This typically involves alkylation of the sample. GC columns, which have been employed for organotin analysis are typically nonpolar PDMS fused silica columns such as HP-1 or the 5% phenyl equivalents such as HP-5.

### Derivatization Techniques for GC Analysis

The two most commonly used derivatization processes used to produce volatile derivatives from sample extracts are Grignard reagents or aqueous phase ethylation procedures with a reagent such as sodium tetraethylborate. Both these reagents convert ionic organotin compounds such as  $\text{R}_n\text{SnCl}_{4-n}$  into non-polar volatile derivatives such as  $\text{R}_n\text{SnEt}_{4-n}$  in the case of ethylation reagents. Sodium tetraethylborate

has become a very common derivatizing reagent for the routine analysis of environmental samples. Grignard derivatizations are still employed by some laboratories utilizing reagents such as pentylmagnesium bromide to transform Sn-Cl groups into Sn-pentyl groups and thus producing a volatile species. Where Grignard derivatization is employed, the sample extract has to be typically dried and reconstituted in a dry aprotic solvent such as diethyl ether before the derivatization can occur. In contrast, sodium tetraethylborate can be used directly on aqueous based extracts with the derivatized species then extracted into a nonpolar solvent such as hexane for GC analysis. Some methods have used hydridization as the derivatization method, however the highly volatile nature of the derivatives makes them more difficult to work with routinely and in general the technique is more applicable to water samples.

## Detection Methods

### Fluorimetric Detection

Organotins are nonfluorescent compounds but fluorescence detection has been applied to the analysis of organotins in conjunction with appropriate derivatization reagents. One of the main problems has been that differently substituted forms of organotins can require different derivatizing reagents and thus generic methods for mono-, di-, and trisubstituted forms of organotins are quite difficult to develop. Despite this, methods for some organotin species in waters, sediments, and biota have been reported.

### Flame Photometric Detector and Pulsed Flame Photometric Detector

Traditional FP detection for organotins typically suffers from interferences from coextracted sulfur and phosphorus compounds, and problems with baseline stability have been reported for more complex matrices such as sediments. The new generation FPDs with a pulsed flame has offered a good method for routine organotin analysis. The higher selectivity available with pulsed flame photometric detector (PFPD) allows the use of a 390 nm optical filter (corresponding to the Sn-C emission) rather than the classical 610 nm (corresponding to the Sn-H emission). This has been observed to significantly reduce the effect of interferences and offers high sensitivity. However, the PFPD has a narrow linear range and samples must often be diluted to allow effective quantification, which can be time consuming.

### Atomic Absorption Spectrometry

AAS has been coupled with both GC and LC separation techniques. With GC separation, AAS is typically used with a quartz furnace following hydride generation. The hydrides are heated in the quartz tube to around 1000°C where they are atomized. Several wavelengths are available for tin determination by AAS using both hollow cathode lamps and electrodeless discharge lamps. Flame, quartz furnace, and electrothermal AAS have all been applied with LC separation, although the interface must cope with a continuous flow of solvent, which is not ideal. In general, AAS has been applied widely to tin speciation but is becoming less popular as it is less able to cope with low level samples and more complex matrices.

### Atomic Emission Spectrometry

AES with a microwave-induced plasma has been a popular technique for organotin analysis allowing very selective detection by utilization of specific Sn emission wavelengths such as 326, 303, or 271 nm. However, the detector can require high maintenance, which can be a drawback for routine use.

### Inductively Coupled Plasma Mass Spectrometry

Mass selective detection does not offer a traditional element-specific detection system as in the above three cases of FPD, AAS, and AES. However, ICP-MS offers excellent sensitivity and selectivity by means of a mass selective filter. Because of the very high selectivity of the detector, sample cleanup can often be minimal. Modern MS instruments have a large dynamic range and can be coupled with either LC or GC systems. Using LC, the commonly used narrow bore columns of 2 mm internal diameter can be easily connected directly to the ICP-MS nebulizer. The major requirement is typically the addition of a significant level of oxygen (~5%) to the argon nebulization gas flow in order to avoid the buildup of carbon deposits within the interface. A cooled spray chamber (~5°C) is also typically employed to minimize the solvent loading on the plasma as high organic solvent levels can cause the plasma to be unstable. Problems with plasma instability mean that isocratic LC mobile phases are preferable, as the organic loading then remains constant.

The large number of tin isotopes (10) means that there is significant choice for ICP-MS analysis, however, a significant number suffer from interferences or low abundances. As a result  $^{120}\text{Sn}$  is the most commonly employed isotope for analysis using  $m/z$  120. The use of ICP-MS detection also allows the primary method of isotope dilution mass spectrometry (IDMS) to be employed. This involves the

addition of an isotopically enriched organotin internal standard, for example,  $^{117}\text{Sn}$ -,  $^{118}\text{Sn}$ -, and  $^{119}\text{Sn}$ -containing organotin can be used for this purpose. This method can provide highly accurate and precise results as the determination depends upon the simple measurement of an isotopic ratio.

GC-ICP-MS is becoming one of the most common techniques for organotin analysis. The required interface to link the GC and ICP is now available commercially and a large number of laboratories have adopted this technique and it is now regularly utilized for organotin analysis. The high resolving power of GC for separation of different species and the excellent selectivity and sensitivity of the ICP-MS detector make this an excellent combination offering a rapid and precise analytical system.

### Other Mass Spectrometry Techniques

LC-MS has been used for organotin analysis, though its application is much less wide spread than ICP-MS. It offers the advantage of providing structural information because of the soft ionization processes employed in the atmospheric pressure interfaces, and molecular ions (or their adducts) are generally observed for organotin species.

High-resolution mass spectrometry has been utilized effectively by coupling a magnetic sector mass spectrometer with GC and an electron impact interface. This provides a highly sensitive and selective detection method but has not been reported for routine use.

### Sampling and Storage

The sampling and storage of collected samples for organotin speciation is highly important, as it is necessary to ensure that minimal species degradation occurs prior to analysis. The sample collection stage is particularly important when low level samples are being analyzed, e.g., at the nanogram per liter or nanogram per kilogram level. Many laboratories have investigated ideal storage conditions. It is recommended that sediments and waters be stored at in the dark at low temperature, typically 4°C. To maximize the long-term stability of water samples, pH adjustment to low pH (e.g., 2) is recommended. Ideally sediments and biota are stored in the freeze-dried state, but this is usually not feasible for routine samples. The filtering of water samples should be avoided as the organotin species are often bound to particulates in water samples. Samples are ideally collected in polytetrafluoroethylene (PTFE), polyethylene, or glass. PVC should be avoided, as dibutyltin is a common stabilizer in PVC materials.

### Sample Cleanup

Many methods involving highly selective detectors do not include a sample cleanup step. Where cleanup is required, techniques such as silica, alumina, or florisil cleanup is often employed to remove coextractives. The extraction of biological tissues can lead to high lipid levels in the extracts, these can be removed using silica cartridges. Silica and alumina have also been used to remove interferents from extracts of organic rich sediments. Water samples are often simply preconcentrated using solid-phase extraction cartridges with stationary phases such as C18.

### Contamination

Contamination of laboratory areas with organotins can be a considerable issue and the appropriate handling and disposal of contaminated articles should be carefully controlled and blank levels should be monitored.

### Standards

Standards for many organotins are available from commercial suppliers with chemical purities of typically 95% or better, however, limited uncertainty information is generally available on these purity values. Care should be taken in the choice of solvent and container which standards are prepared in to minimize any absorption onto the walls. Stock solutions are typically prepared in methanol and refrigerated. Working-level solutions are often prepared regularly, even daily.

### Calibration

The calibration technique of standard addition is often used to minimize matrix effects in the quantification of organotins. External calibration is also used by many groups, however, the use of an internal standard is highly recommended with the nature of the best compound to use dependent on the measurement system involved. Tripropyltin chloride has been used by many groups as a surrogate to monitor the whole method process, and species such as tetra-butyltin and tetrapentyltin have been used as internal standards added just prior to GC analysis.

Several laboratories have prepared isotopically enriched organotin species to use as internal standards in the technique of isotope dilution analysis. This MS technique can provide higher levels of accuracy than other calibration techniques and is currently used in many reference laboratories.

## Certified Reference Materials

In order to validate speciation methods more effectively, a number of certified reference materials (CRMs) have been produced to allow laboratories to measure the accuracy of their techniques. A range of sediment and biota materials are available such as the sediment materials PACS-2 from the National Research Council of Canada, NIES-12 from the National Institute for Environmental Studies, Japan and the CRM-462 from Community Bureau of Reference (BCR), EU. These materials have been rigorously homogeneity and stability tested and the levels of organotins have been certified by a range of techniques utilizing either 'definitive' methods or multiple independent methods.

## Introduction

A titration is defined as 'the process of determining the quantity of a substance A by adding measured increments of substance B, the titrant, with which it reacts until exact chemical equivalence is achieved

(the equivalence point)'. The titrant is usually added as a standardized solution, but electrolytic generation, as in coulometric titrations, is also possible.

The achievement of the equivalence point is indicated in one of two ways. The first is visually, for example, by the addition of an indicator, which changes color, or by fluorescence or a similar property at or close to the equivalence point. The change indicates the endpoint of the titration, and the indicator should be chosen so that the endpoint is as close as possible to the equivalence point. The second method is to measure a physical property of the solution being titrated (e.g., conductivity, pH, absorbance) and identify the equivalence point by processing the signals obtained. The latter approach is particularly useful when titrations are automated.

The amount of titrant added is usually measured by volume (by dispensing the solution from a burette), and in this case, titrimetry is an example of volumetric analysis. Occasionally, the titrant is measured by weight (especially if greater accuracy is required) or by amount of electricity (as in coulometric titrations).

Titrimetry is one of the oldest analytical techniques, originating in the middle of the eighteenth century as a rapid means of quality control of industrial processes, such as acid manufacture. Since that time, the equipment has been refined, the procedures have been automated, and the number of chemical reactions utilized greatly increased, but the basic principles are unchanged. Its continued popularity stems from the simplicity of equipment and execution, wide applicability, and high accuracy and precision (greater than most instrumental techniques), all of which make it particularly applicable to the determination of major and minor components of samples. Skilled titrimetric analysis should give results with a precision of  $<0.2\%$  at the  $1 \times 10^{-2} \text{ mol l}^{-1}$  level.

Titrimetry may be classified with respect to the types of reaction that are involved. The major reactions are acid–base reactions (hence acid–base titrimetry), redox reactions (redox titrimetry), complexing reactions (compleximetric titrimetry), and precipitation reactions (precipitation titrimetry), which will be discussed in more detail below.

Titrimetry may also be classified by the nature of the endpoint measurement. The use of electrical measurements gives rise to potentiometric, amperometric, and coulometric titrations. Measurement of heat changes is used in thermometric titrimetry, and of absorbance in photometric and turbidimetric titrations. Radiometric titrations measure changes in radioactivity during the titration. All of these techniques are dealt with in other articles in this Encyclopedia. This article discusses only those titrations that use visual indicators.

## General Manual Titrimetric Technique

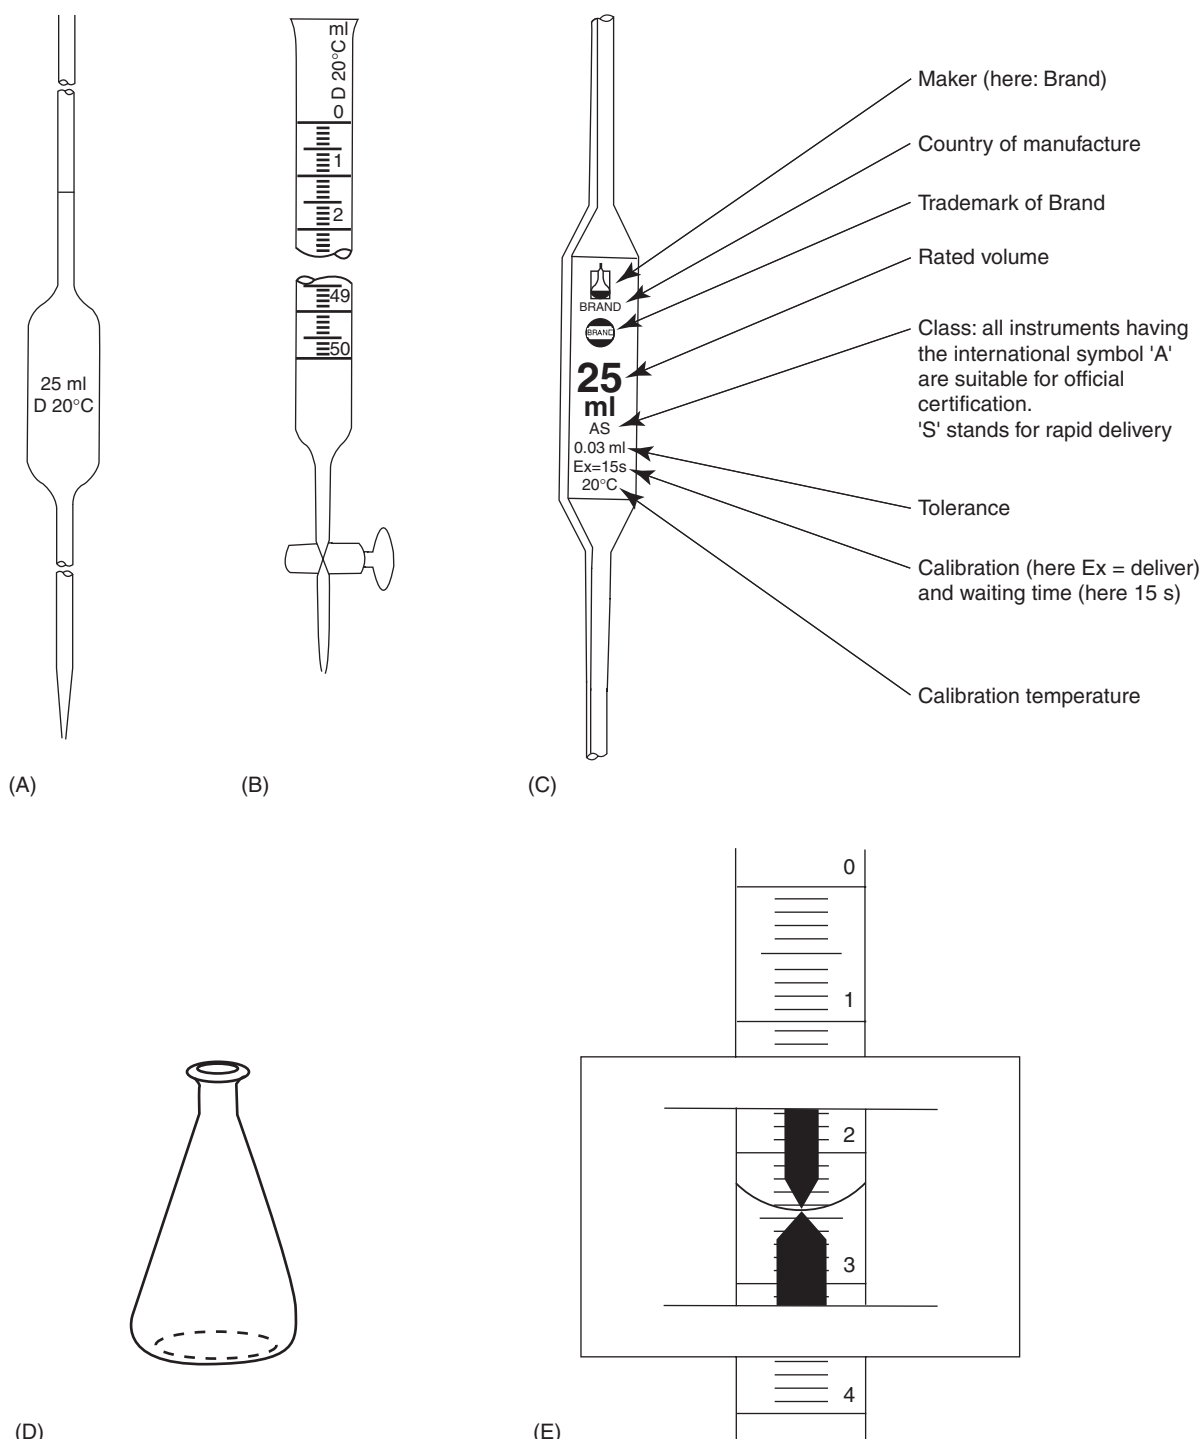

The simple equipment used for a typical titration is shown in **Figure 1**. A sample is measured into the flask from a pipette, or by weighing. The accuracy and precision of manual titrations using visual indicators is critically dependent on the use of correct experimental technique by the analyst. As in most analytical procedures, precise measurement of the amount of sample (or sample aliquot) is necessary, but it is most important in titrimetry if an accuracy of  $<0.2\%$  is to be achieved. Thus, proper use of the pipette, burette, and balance, and a careful sample preparation procedure is crucial. Measurement devices of high quality, such as class A pipettes and burettes, should be used.

When carrying out a titration the burette, holding the titrant solution, is clamped vertically just above the flask. Generally, the flask containing the solution being titrated should be placed on a white tile. Where the color change is somewhat difficult to detect, a reference solution should be used for comparison (this is a solution held in a flask similar to that being used for the titration, has the same volume, contains the same indicator, and has been adjusted to the endpoint). Titrant is added from the burette to the solution in the flask, which is then swirled by hand. As the endpoint approaches (which will be signaled by a transient color change in the portion of the solution where the titrant is added), the titrant should be added dropwise. When very close to the endpoint, fractions of drops can be added by touching the tip of the burette with a partly formed drop on the inside of the flask, and washing down with water from a wash bottle. The detection of the endpoint, when using a 50 or 10 cm<sup>3</sup> burette, should be possible to within 0.02 cm<sup>3</sup>. The volume of titrant run out of the burette is used to calculate the concentration of analyte in the titrated solution.

## Standards

Titrimetric analysis depends upon the availability of solutions of accurately known concentration for use as titrants. Such standard solutions may be prepared and themselves standardized by titration with solutions prepared from materials of guaranteed purity and composition, preferably solutions of chemicals known as primary standards. These materials have the following properties, as listed by Dodge:

1. They are easily obtained in an analytically pure state.

**Figure 1** Equipment used for a manual titration. (A) Transfer pipette; (B) burette; (C) information provided on volumetric glassware; (D) conical or Erlenmeyer flask (normally 250 or 100 cm<sup>3</sup>); (E) burette reader. (Reproduced with permission from Belcher *et al.* (1970) and Rudolf Brand and Co. *Working with Volumetric Instruments*. Wertheim: Brand.)

2. They should be unalterable in air at ambient or moderately high temperatures.
3. They should have a high equivalent weight, thus decreasing the effect of small weighing errors.
4. They should be readily soluble under the conditions of the analysis, thus allowing immediate titration in the cold.
5. On titration, no interfering product should be present.

**Table 1** Some primary titrimetric standards

Compound		Type	Type of titration
Name	Formula		
Anhydrous sodium carbonate	$\text{Na}_2\text{CO}_3$	Weak base	Acid–base
Sodium borate (borax) (recrystallized)	$\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$	Weak base	Acid–base
Sulfamic acid	$\text{NH}_2\text{SO}_3\text{H}$	Strong acid	Acid–base
Potassium hydrogenphthalate	$\text{KHC}_8\text{H}_4\text{O}_4$	Weak acid	Acid–base
Potassium hydrogenbiiodate	$\text{KH}(\text{IO}_3)_2$	Strong acid	Acid–base
Silver nitrate	$\text{AgNO}_3$		Argentimetric
Sodium oxalate	$\text{Na}_2\text{C}_2\text{O}_4$	Reductant	Redox
Arsenic(III) oxide	$\text{As}_2\text{O}_3$	Reductant	Redox
Potassium dichromate	$\text{K}_2\text{Cr}_2\text{O}_7$	Oxidant	Redox
Ammonium hexanitrocerate(IV)	$(\text{NH}_4)_2\text{Ce}(\text{NO}_3)_6$	Oxidant	Redox
Potassium iodate	$\text{KIO}_3$	Oxidant	Redox
Potassium bromide	$\text{KBrO}_3$	Oxidant	Redox
Calcium carbonate	$\text{CaCO}_3$	Source of calcium ions	Compleximetric
Zinc oxide	$\text{ZnO}$	Source of zinc ions	Compleximetric
Ni, Zn, Cu metals	Ni, Zn, Cu	Source of metal ions	Compleximetric
Anhydrous disodium EDTA	$\text{C}_{10}\text{H}_{14}\text{N}_2\text{O}_8\text{Na}_2$	Complexing agent	Compleximetric

6. They should be colorless, before and after titration, to avoid interference with indicators.

Primary standards for particular titrations are given in Table 1. There are relatively few compounds that satisfy all these conditions.

It is also possible to buy concentrated standard solutions, which, after accurate dilution, can be used for titrimetry.

## Acid–Base Titrations

In acid–base titrations, an acid is determined by titration with a base, or vice versa. The essential reaction is between  $\text{H}^+$  and  $\text{OH}^-$ , giving water. The pH at the endpoint depends on the dissociation constants of the reactants and products. Thus, the titration of a strong, i.e., completely dissociated, acid with a strong, almost completely dissociated, base reaches equivalence at pH 7.0. A typical example is the titration of hydrochloric acid with sodium hydroxide solution. If a weaker, i.e., less dissociated base, such as ammonia, is used, the equivalence pH is  $< 7.0$ ; the weaker the base, the lower the equivalence pH. Likewise, if a weak, i.e., less dissociated, acid is titrated with a strong base, the equivalence pH is  $> 7.0$ , the pH increasing with increasing weakness of the acid. For the titration of a weak acid with a weak base, the equivalence pH depends on the relative dissociation constants of the acid and base, but the limited pH change means that the equivalence point is not as sharp as in a strong acid or strong base titration. The change of pH during the course of such titrations is illustrated in Figures 2 and 3.

**Figure 2** Titration of 10 ml of hydrochloric acid of various concentrations with sodium hydroxide solution of the same concentration. (Redrawn from Belcher *et al.* 1970.)

The extent of the pH change also depends on the concentration of the analyte and titrant. Figure 2 shows how the pH change decreases with decreasing concentration of HCl and NaOH. The indicators for such titrations are chosen to change color very close to the pH at equivalence, and are described in detail in a separate article.

Some acids are polybasic, i.e., they give rise to more than one hydrogen ion. Phosphoric acid, for

**Figure 3** Titration of 10 ml of  $0.1 \text{ mol l}^{-1}$  acetic acid with (A)  $0.1 \text{ mol l}^{-1}$  sodium hydroxide; (B)  $0.1 \text{ mol l}^{-1}$  ammonia. (Redrawn from Belcher *et al.* 1970.)

**Figure 4** Titration of 25 ml of  $0.1 \text{ mol l}^{-1}$   $\text{H}_3\text{PO}_4$  with  $0.1 \text{ mol l}^{-1}$  NaOH. (Redrawn from Belcher *et al.* 1970.)

**Table 2** Examples of acid–base titrimetric analyses

Analyte	Titrant	Indicator	Conditions
$\text{CaCO}_3$	HCl	Methyl red or phenolphthalein	–
$\text{H}_3\text{PO}_4$	NaOH	Methyl orange	First endpoint
		Thymolphthalein	Second endpoint
$\text{NH}_4^+$	HCl	Methyl red	Distillation from NaOH solution
Boric acid	NaOH	Phenolphthalein	Binding with mannitol or sorbitol to increase acidity

example, produces three hydrogen ions:

The change in pH on titration with NaOH is shown in **Figure 4**. The first dissociation (reaction [I]) occurs most easily, and titration with NaOH gives an equivalence point at pH 4. Further titration, of the second, more strongly bound hydrogen ion (reaction [II]), also gives rise to an equivalence point, at pH 9. The third hydrogen ion does not give rise to a sharp endpoint. Thus, phosphoric acid may be determined by titration to the first or second endpoints.

Some examples of acid–base titrimetric analyses are given in **Table 2**.

## Precipitation Titrations

These are titrations in which the analyte and titrant react to form a precipitate. The only common titrant used is silver nitrate (argentimetric titrations), and its use is mainly restricted to the determination of

chloride, bromide, iodide, cyanide, and thiocyanate, although in principle any species that is precipitated by silver ions could be determined. Direct titrations involve the use of potassium chromate (Mohr's method) or fluorescein derivatives as indicator. An indirect (back-titration) procedure is also popular, in which excess of precipitant ( $\text{Ag}^+$ ) is added to the sample, and the unreacted  $\text{Ag}^+$  titrated with thiocyanate ions (Volhard's method), using iron(III) as indicator. The mechanisms of the indicator reactions are described in another article.

## Redox Titrations

In these titrations, a reducing agent is titrated with an oxidizing agent, or vice versa. The common oxidizing titrants are potassium permanganate ( $\text{KMnO}_4$ ), potassium dichromate ( $\text{K}_2\text{Cr}_2\text{O}_7$ ), cerium(IV) sulfate ( $\text{Ce}(\text{SO}_4)_2$ ), iodine ( $\text{I}_2$ ), potassium iodate ( $\text{KIO}_3$ ), and potassium bromate ( $\text{KBrO}_3$ ), all of which are solids, and sodium hypochlorite ( $\text{NaClO}$ ), which is available as a solution. The most important reducing titrants are iron(II) salts, often ammonium iron(II) sulfate ( $(\text{NH}_4)_2\text{Fe}(\text{SO}_4)_2 \cdot 6\text{H}_2\text{O}$ ), sodium thiosulfate ( $\text{Na}_2\text{S}_2\text{O}_3 \cdot \text{H}_2\text{O}$ ), and arsenic(III) oxide ( $\text{As}_2\text{O}_3$ ).

The stoichiometry of the reaction between one of these titrants and a particular analyte is established by combining the appropriate half-reactions. For the titrants above, the half-reactions are as follows:

### Oxidants

### Reductants

For example, iron(II) can be determined by titration with dichromate, so combination of the appropriate half-reactions [VII] and [XIII], so as to achieve a charge and mass balance, gives the overall reaction [XVI]:

The driving force for each half-reaction is measured by its oxidation potential,  $E$ , measured in V, which is

given by the Nernst equation:

$$E = E_0 + \frac{0.059}{n} \log \frac{[\text{ox}]}{[\text{red}]} \quad [1]$$

where  $n$  is the number of electrons involved in the above half-reaction, and [ox] and [red] are the concentrations (or better, activities) of the oxidized and reduced forms of the species, respectively.  $E_0$  is a constant known as the standard potential, which is the idealized potential when [ox] = [red]. A similar parameter, but measured under actual experimental conditions, is known as the formal potential ( $E_F$ ), and is more immediately useful for application in redox titrimetry. Some potentials for the above half-reactions are given in parentheses in the above equations.

The change in oxidation potential during the titration of a reductant (iron(II)) by an oxidant (cerium(IV)) is shown in Figure 5. The final oxidation potential increases with the strength of the oxidant used. Sometimes, it is possible to make a simple calculation of the equivalence potential ( $E_{EP}$ ) as follows. For the reaction that can be written as in [XVII]:

then

$$\begin{aligned} E_{EP} &= \frac{E_F(\text{Ce}^{4+}/\text{Ce}^{3+}) + E_F(\text{Fe}^{3+}/\text{Fe}^{2+})}{2} \\ &= \frac{1.44 + 0.68}{2} \\ &= 1.06 \text{ V} \end{aligned} \quad [2]$$

**Figure 5** Titration of 25 ml of  $0.1 \text{ mol l}^{-1}$  iron(II) with  $0.1 \text{ mol l}^{-1}$  cerium(IV). (Redrawn from *Vogel's Textbook of Quantitative Inorganic Analysis*, 4th edn (1978). London: Longman.)

For more complex systems, however, especially those involving oxoanions, such simple calculations are not valid.

Indicators for redox titrations will be chosen to change color reversibly by oxidation or reduction at a potential as close as possible to the equivalence potential (starch indication for iodine is an exception). This aspect is described in detail in another article.

Some analytes may be determined by titration with an oxidant, after their reduction. There are several ways of carrying out such reductions. One commonly used reductant is tin(II) chloride, in which the excess of tin(II) is destroyed by addition of mercury(II) chloride:

The mercury(I) chloride is unaffected by oxidants during the subsequent titration. Sulfite (or  $\text{SO}_2$ ) and hydrogen sulfide are alternative reductants. Metals may also be used. Small pieces of metal (zinc – a Jones reductor, silver – a Walden reductor) are used to fill a column, through which the analyte solution is passed. The effluent is titrated with oxidant. A comparison of the reduction products of the two reductor columns is given in Table 3.

**Table 3** Comparison of the Jones and Walden reducers

Walden (HCl)	Jones ( $\text{H}_2\text{SO}_4$ )
$\text{Fe(III)} \rightarrow \text{Fe(II)}$	$\text{Fe(III)} \rightarrow \text{Fe(II)}$
Ti(IV) not reduced	$\text{Ti(IV)} \rightarrow \text{Ti(III)}$
Cr(III) not reduced	$\text{Cr(III)} \rightarrow \text{Cr(II)}$
$\text{V(V)} \rightarrow \text{V(IV)}$	$\text{V(V)} \rightarrow \text{V(II)}$
$\text{Mo(VI)} \rightarrow \text{Mo(V)}$	$\text{Mo(VI)} \rightarrow \text{Mo(III)}$
$\text{Cu}^{2+} \rightarrow \text{Cu(I)}$	$\text{Cu}^{2+} \rightarrow \text{Cu(0)}$

Redox titrations are still widely used. Table 4 summarizes some applications of redox titrations.

## Compleximetric Titrations

Compleximetric titrations are used mainly to determine metal ions by use of complex-forming reactions. Although in theory many complexing agents (cyanide, thiocyanate, fluoride, 1,2-diaminoethane, etc.) could be used for this purpose, in practice the titrants are almost always compounds having the iminodiacetic acid functional group:

and by far the most popular of these is ethylenediaminetetraacetic acid (EDTA):

This ligand fulfills many of the qualities of a good compleximetric titrant. It forms complexes with most metal ions (those with the alkali metals are too weak to be useful); all the complexes have exact 1:1 stoichiometry, because the ligand is hexadentate, and can therefore occupy up to six coordination positions on the metal ions, as shown in Figure 6. The reaction with most metal ions is rapid ( $\text{Cr}^{3+}$  is a well-known exception), and the complexes are water

**Table 4** Examples of redox titrations

Analyte	Titrant	Indicator	Condition
Iron(II)	$\text{KMnO}_4$	Self-indicating	$\text{SnCl}_2$ reduction
Iron(III)	$\text{KMnO}_4$	Self-indicating	
$\text{H}_2\text{O}_2$	$\text{KMnO}_4$	Self-indicating	
Iron	$\text{K}_2\text{Cr}_2\text{O}_7$	Diphenylamine sulfonic acid	In iron ore, $\text{SnCl}_2$ reduction
Ethanol	$\text{K}_2\text{Cr}_2\text{O}_7$	<i>N</i> -Phenylanthranilic acid	Add excess oxidant, heat, back-titrate with iron(II)
Oxalate	$\text{Ce(SO}_4)_2$	Nitroferroin	Add excess oxidant, heat, back-titrate with iron(II)
Nitrite	$\text{Ce(SO}_4)_2$	Ferroin	Add excess oxidant, back-titrate with iron(II)
Copper(II)	$\text{Na}_2\text{S}_2\text{O}_3$	Starch	Iodide oxidized to iodine
Acids	$\text{Na}_2\text{S}_2\text{O}_3$	Starch	$5\text{I}^- + \text{IO}_3^- + 6\text{H}^+ \rightarrow 3\text{I}_2 + 3\text{H}_2\text{O}$
Available chlorine	$\text{Na}_2\text{S}_2\text{O}_3$	Starch	Oxidation of $\text{I}^-$ to $\text{I}_2$
Antimony(III)	$\text{I}_2$	Starch	Precipitate $\text{Mg}^{2+}$ with 8-quinolinol, add excess $\text{KBrO}_3/\text{KBr}$ to brominate precipitate, determine excess $\text{KBrO}_3$ by oxidation of $\text{I}^- \rightarrow \text{I}_2$
Magnesium(II)	$\text{Na}_2\text{S}_2\text{O}_3$	Starch	
Ascorbic acid	$\text{KIO}_3$	Self-indicating ( $\text{I}_2/\text{CCl}_4$ )	Add $\text{Br}^-$ and excess $\text{NaClO}$
Ammonia	$\text{NaClO}$	Bromothymol blue	

**Figure 6** Structure of chelate of EDTA anion ( $L^{4-}$ ) with a metal ion  $M^{2+}$ . (Redrawn from *Vogel's Textbook of Quantitative Inorganic Analysis*, 4th edn (1978). London: Longman.)

soluble and colorless (unless the metal ion itself is colored).

The reaction between a typical metal ion and EDTA ( $H_4L$ ) can be written as

that is, as a competition between the metal ion and hydrogen ions for binding with  $L^{2-}$ . The stability of binding of  $M^{n+}$  with  $L^{2-}$  is measured by its stability constant  $k_1$ , which is the equilibrium constant for the reaction:

$$k_1 = \frac{[ML^{(4-n)-}]}{[M^{n+}][L^{4-}]} \quad [3]$$

where  $[ ]$  denotes concentrations (better, activities).

Some typical stability constants are given in **Table 5**. Metals forming weaker complexes, therefore, require less acidic (i.e., higher pH) conditions for complex formation. The optimum pH values for the titration of a number of metal ions are included in **Table 5**. Metals forming stronger complexes can be titrated at lower pH values, at which the weaker complexing metals do not react, thus selective titration of, for example, bismuth can be carried out in the presence of lead at pH 1–2. The reaction of metal ions with EDTA (reaction (XIX)) generates  $H^+$ . Thus, to prevent a pH change during the titration, the solution must be adequately buffered.

**Table 5** Stability constants of some EDTA complexes and optimum pH for titration of the metal ions with EDTA

Metal ion	$\log k_1$	Optimum pH for titration
$Mg^{2+}$	8.7	10
$Ca^{2+}$	10.7	7.5
$Ba^{2+}$	7.8	12–13
$Mn^{2+}$	13.8	5.5
$Zn^{2+}$	16.5	4
$Ni^{2+}$	18.6	3
$Co^{2+}$	16.3	4
$Fe^{2+}$	14.3	5
$Fe^{3+}$	25.1	1
$Cu^{2+}$	18.8	3
$Hg^{2+}$	21.8	5.0–5.5 <sup>a</sup>
$Pb^{2+}$	18.0	4
$Bi^{3+}$	27.9	1–3

<sup>a</sup>The behavior of  $Hg^{2+}$  is somewhat anomalous because of hydroxocomplex formation. Values obtained from Pribil (1982).

**Figure 7** Two alternative titrants to EDTA.

Adjustment of pH often will not give sufficient selectivity and, of course, is inappropriate if a weaker-complexing metal ( $M_W$ ) has to be titrated in the presence of a more strongly complexing metal ( $M_S$ ). In such circumstances it is possible to 'mask'  $M_S$  by adding another complexing agent that complexes much more strongly with  $M_S$  than with  $M_W$ , so that  $M_W$  but not  $M_S$  will react with EDTA. The use of such masking agents is widespread in compleximetric titrimetry. A typical example is the use of triethanolamine to mask iron(III) when calcium is titrated with EDTA in alkaline solution.

A wide range of visual indicators is available for compleximetric titrations. These generally function by forming a colored complex with the metal ion being titrated, which causes a color change when the metal ion is removed from the complex by reaction with EDTA and releases the free ligand. These indicators are described in detail in another article.

Other EDTA-type compounds are sometimes used as titrants, including 1,2-diaminocyclohexane- $N,N,N',N'$ -tetraacetic acid, which generally forms stronger complexes than EDTA, and nitrilotriacetic acid, which generally forms weaker complexes than EDTA (**Figure 7**).

## Nonaqueous Titrimetry

Most titrations are carried out in aqueous solution, including all those described above. In some circumstances, however, it is advantageous to use other solvents, especially organic solvents. Such nonaqueous titrations are normally used for acid–base reactions, but redox reactions may also be applicable. The Karl–Fischer titration of water, in particular, is based upon redox reactions in a nonaqueous medium.

The ionization of a molecule HB in a solvent S is influenced by the solvation of the ions:

The ease of dissociation to form  $\text{HS}^+$  (solvated  $\text{H}^+$ ) increases with increasing basicity of the solvent, i.e.,

**Figure 8** Apparatus for visual titration with nonaqueous solvents. Automatic burette protected with guard tubes; a guard tube and blow-bulb are attached to the bottom outlet of the burette. The nitrogen flow can be omitted for titrations in acidic solvents. (Redrawn from Belcher *et al.* 1970.)

with increasing binding strength between  $\text{H}^+$  and the solvent. Thus, an acid that is very weak in aqueous solution will be stronger in a more basic solvent such as pyridine or dimethylformamide, and will give a bigger ‘pH’ change on titration. Phenols, for example, which are too weak acids to be titrated in aqueous solution, can be titrated in pyridine solution with tetrabutylammonium hydroxide in benzene–methanol (9:1, v/v) as titrant, and thymolphthalein in methanol as indicator.

Similarly, bases that are very weak in aqueous solution (e.g., amines) show increased basicity in solvents of greater acidity, such as anhydrous acetic acid. Perchloric acid in acetic acid may be used as the titrant, with crystal violet in acetic acid as indicator.

Because many of the solvents used are aggressive, volatile, and obnoxious, nonaqueous titrations are normally carried out in a closed environment, which also minimizes the ingress of moisture (**Figure 8**). It is essential to ensure that all apparatus used is dry and, especially for titrations in basic solvents, a stream of nitrogen is used to prevent access of carbon dioxide to the solution being titrated. The titrant is stored in a reservoir connected directly to the burette.

Compounds that may be determined by nonaqueous titrimetry include amines, amino acids, phenols, and Schiff’s bases. Carbonyl compounds (by oxidation and titration of the released  $\text{H}^+$ ) can also be determined. Such titrations are especially useful in the pharmaceutical industry.

## Potentiometric

**A Hulanicki and S Głąb**, University of Warsaw, Warsaw, Poland

### Introduction

A potentiometric titration belongs to chemical methods of analysis in which the endpoint of the titration is monitored with an indicator electrode that records the change of the potential as a function of the amount (usually the volume) of the added titrant of exactly known concentration. Potentiometric titrations are especially versatile because indicator electrodes suitable for the study of almost every chemical reaction used in titrimetry are now available. This technique is also frequently used in the study of operational conditions of visual titrimetric indicators proposed for general use in chemical analysis, as well as in the study of numerous reactions, such as protonation and complexation, which find their application not particularly in analytical measurements. The course of the potentiometric titration curve provides information not only about the titration endpoint position, but also the position and shape of the curve that may provide data about the processes accompanying the titration reaction. Another advantage is that the necessary apparatus is generally less expensive, reliable, and readily available in the laboratories.

### Potentiometric Equipment

Applications of potentiometry involve the use of an electrochemical cell consisting of a reference electrode of constant potential and an indicator electrode that responds to the analyte studied and sample composition. The electromotive force (e.m.f.) of this cell can be regarded as the difference of the potentials of the two electrodes (half-cells).

#### Indicator Electrodes

**pH-sensitive electrodes for acid–base titrations** The glass electrode is most often used but occasionally metal–metal oxide (e.g., antimony electrode) and pH-sensitive polymeric membrane electrodes are also used. These electrodes are also useful in investigation of chemical reactions through potentiometric titrations, as in many of them their course can be traced by the changes of hydrogen ion activity (concentration).

**Electrodes for precipitation titrations** The choice of the electrode depends on the character and properties of ions taking part in the titration reaction. Common

is the use of silver or mercury electrodes of the first order to trace the respective metal ions, or as the second-order electrodes, silver–silver halide and mercury–mercury(I) halide electrodes, when the corresponding anions are involved in the reaction. Metal electrodes with sulfide (or other sulfur(II) containing species) as co-anion are used less often. There is also a large group of ion-selective electrodes (ISEs) sensitive to  $F^-$ ,  $Cl^-$ ,  $Br^-$ ,  $I^-$ ,  $S^{2-}$ ,  $Cu^{2+}$ ,  $Pb^{2+}$ , and  $K^+$ , which are used to monitor precipitation titrations of both inorganic and organic ions.

**Electrodes for compleximetric titrations** Electrodes respond mainly to change of metal ion concentration, similarly as electrodes used in precipitation reactions. Occasionally, the electrode responds to the ligand, as is the case of the fluoride ISE. Electrodes with a similar scheme as the electrode of third order ( $Ag/Ag_2C_2O_4/CaC_2O_4/Ca^{2+}$ ) can be used in compleximetric titration, having as an intermediate step the equilibrium with the appropriate ligand (e.g.,  $AgEDTA/MEDTA$ ), where M denotes the metal ion being titrated. There is additionally a large group of ISEs that respond to the metal ions. As complexation with protonated ligands is accompanied by pH changes, pH-sensitive electrodes are occasionally used.

**Electrodes for redox titrations** For direct measurements of changes of the oxidation–reduction potentials inert electrodes such as bright platinum or gold are mainly used. Iridium and tungsten electrodes can also be used for measuring the redox potentials; however, the kinetic effects may influence the response. The practical application of mercury as an inert electrode is limited to regions of negative redox potentials, but in this region it has a definite advantage over the noble metal electrodes. This is connected with the high hydrogen overpotential on mercury.

#### Reference Electrodes

Most commonly used reference electrodes are based on mercury (calomel electrode) and silver, in equilibrium with the saturated solution of the corresponding chlorides. Their potential will be constant if the chloride ion concentration around the electrode is constant. The mercury–mercury(I) sulfate electrode is used instead of the calomel electrode when the presence of chloride is undesirable.

#### Instrumentation

The experimental instrumentation for potentiometric titration consists primarily of a high-impedance

electronic pH or millivolt meter, a beaker and a magnetic stirrer, indicator and reference electrodes, and a burette for titrant delivery, which are needed for manual titrations and point-by-point plotting. Automatic burettes and direct curve recording devices are increasingly used, in particular when the decrease of the scale of the titration is expected to go down below 1 ml of the amount of titrant used up to the endpoint. A variety of instruments are commercially available. In general, pH (or potential) meters can be divided on the basis of price and performance: utility (portability), general purpose, expanded scale, and research grades.

## Potentiometric Titration Curves

Potentiometric titration curves are obtained by plotting the potential of the indicator electrode (in practice the e.m.f. of the cell) against the volume of the titrant. In acid–base titrations, the pH value is usually plotted instead of the potential. The logarithmic shape of the titration curve is a consequence of the logarithmic dependence of activity or activity ratio of the species participating in the titration reaction according to the Nernst equation:

$$E = E^0 + \frac{RT}{zF} \ln \frac{a_{\text{ox}}}{a_{\text{red}}}$$

where  $a_{\text{ox}}$  represents the oxidant activity and  $a_{\text{red}}$  the reductant activity. When the activity of one of those species is constant, the activity ratio is simply replaced by the activity of the ion sensed by the indicator.

From the shape and position of the titration curve along the potential axis, information can be gained

about the parameters of the titration reaction. For example, in alkalimetric titration of an acid the pH value of the half-neutralization of the acid corresponds numerically to the  $\text{p}K_{\text{a}}$  value of the acid. This makes possible the evaluation of the  $\text{p}K_{\text{a}}$  value of the titrated species. Similarly, in other types of titrations (precipitation, compleximetric, and redox) the titration curve may supply information about the relevant titration reaction.

In the case of an ideal indicator electrode, such a curve should correspond to the change of the indicator ion activity. In practice, the curve is often distorted because of changes of liquid junction potential and insufficient selectivity of the electrode (especially for ISEs) and occurrence of processes not described by the Nernst equation. Nevertheless, in most cases it does not influence the evaluation of the endpoint. A potentiometric titration curve should have a symmetrical ‘S’ shape, when the dilution effect is neglected, and the indicator electrode is directly sensitive to the ion titrated. If the course is traced indirectly, e.g., in a compleximetric titration of nickel using a copper-selective electrode, the curve is asymmetric (Figure 1). Another reason for the asymmetry of the curve is the asymmetry of the titration reaction, which mostly occurs in redox titrations when the number of electrons in the reaction of the oxidant (e.g.,  $\text{MnO}_4^- \rightarrow \text{Mn}^{2+}$ ) is not equal to the number of electrons exchanged by the reductant (e.g.,  $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$ ). Unusual shapes of the titration curve may occur when the titrated substance is directly inactive but after the addition of the titrant is gradually transformed into an active form in a kinetically restricted reaction. Such situations may occur also

**Figure 1** (A) Symmetric titration curve: compleximetric titration of copper ion, using a copper-selective electrode. (B) Asymmetric titration curve: compleximetric titration of nickel using a copper-selective electrode.

when catalytic processes occur. An improved and rapid potential change is observed when an indicator reaction is catalyzed by the small excess of the titrant. This can be exemplified by silver determination using iodide as titrant. The indicator reaction:  $\text{Ce(IV)} + \text{As(III)} = \text{Ce(III)} + \text{As(V)}$ , followed by a redox electrode, is catalyzed by the presence of free iodide ions, which appear just after the completion of the reaction between silver and iodide.

### Endpoint Evaluation

The endpoint of a titration is an experimentally estimated value, whereas the equivalence point corresponds to the theoretical amount of the titrant that is exactly equivalent to the amount of the analyte. The difference between the endpoint and the equivalence point should be minimized and is referred as the titration error.

The endpoint of the titration is often evaluated on the basis of a graphically represented titration curve. When the potential (or pH) change is large and the curve steep, the endpoint can be easily seen and evaluated. For less obvious cases of symmetrical titrations, several graphical methods of finding the point of maximal slope were used. Another method is titration to a fixed potential. The equivalence-point concentration of the indicator ion may be calculated from the known reaction equilibrium constants, and the corresponding potential values are subsequently evaluated. The equivalence point potential may also be estimated empirically. Titration is continued until this potential is reached, and the volume of the titrant noted. The maximum slope of the titration curve is easily found by plotting the first derivative curve,  $dE/dV$ , or the second derivative curve,  $d^2E/dV^2$ , against the titrant volume,  $V$  (Figure 2). In practice, this can be done for finite increments and the curve is approximated by plotting  $(E_n - E_{n+1})/(V_n - V_{n+1})$  against  $0.5(V_n + V_{n+1})$ , where  $n$  represents the successive additions of titrant. The numerical procedure termed the Hahn method is based on the same

principle. Computerized titrations can achieve the same goal without calculation by the analyst. It must be pointed out that such procedures are exactly valid for symmetrical curves only.

The common procedure of finding the endpoint, which should correspond to the equivalence volume, is based on the Gran method. This procedure is especially useful for flat and unsymmetrical titration curves. The titration data are transformed in such a way that the titration curve consists of two linear parts – before and after the equivalence point. The intersection of those lines or their intersection with the abscissa defines the equivalence volume of the titrant (Figure 3). The linearization is based on the transformation of the Nernst equation into the form

$$\text{antilog}(E/S) = \text{constant} \cdot a_X$$

where the constant is  $\text{antilog}(E^0/S)$ , and  $S = RT/2.303F$ . The straight line is obtained when the increase of volume ( $V_0 + V$ ) is taken into account. Any deviation from linearity may indicate the occurrence of another reaction, either preceding or following the main reaction.

### Single Point Titration

This procedure is based on two potential measurements, one directly using the sample solution ( $E_1$ ) and another on the sample solution with addition of a known amount of analyte ion ( $E_2$ ). This is also

**Figure 3** Titration of two-component mixture: (A) titration curve; (B) linearization according to the Gran method.

**Figure 2** (A) Titration curve plotted in coordinates: potential,  $E$ , versus titrant volume,  $V$ . (B) First-derivative curve,  $dE/dV$ , versus  $V$ . (C) Second-derivative curve,  $d^2E/dV^2$ , versus  $V$ .

termed the known (or standard) addition method. For successful application of this method certain conditions are required:

1. The activity coefficient of the indicator ion should not vary significantly between the two measurements.
2. The side-reaction coefficient of the indicator ion, i.e., the ratio of the free determinand to all its chemical forms, should be constant.
3. The calibration slope of the electrode ( $S = RT/F$ ) must be known and constant.

When these conditions are fulfilled,

$$E = E_2 - E_1 = S \log(V_S C_X + V_A C_A) [C_X (V_S + V_A)]^{-1}$$

where  $V_S$  and  $V_A$  are volumes of sample and of the addition respectively.  $C_X$  and  $C_A$  are unknown and addition concentrations, respectively. This enables  $C_X$  to be calculated as

$$C_X = \frac{C_A V_A}{V_A + V_S} \left( 10^{E/S} - \frac{V_A + V_S}{V_A} \right)^{-1}$$

which for negligible volume of addition ( $V_A \gg V_S$ ) simplifies to

$$C_X = C_A (10^{E/S} - 1)^{-1}$$

A reverse method is based on the removal of the determinand and is called the known (or standard) subtraction method. The removal of the determinand is based on its precipitation or complexation. The necessary condition is that the reaction must be as complete as possible.

Potentiometric titrations may be also performed in the flow injection mode. This is attractive because small amounts of sample are needed, the time of determination is short, and the results for low concentration are reliable. Besides, the potentiometric signal depends linearly on the concentration of the analyte, enabling determination in a broad concentration range. There are several types of such titration, e.g., a fixed sample volume is mixed with a titrant solution of constant concentration. The width of the potentiometric signal, measured on the time scale as  $\Delta t$ , is proportional to the logarithm of the analyte concentration. The quantitative evaluation is based on a calibration graph. The important factors are the linear range of determination and the time constant of the potentiometric detector. The latter must be compatible to the flow rate of the solution in the system.

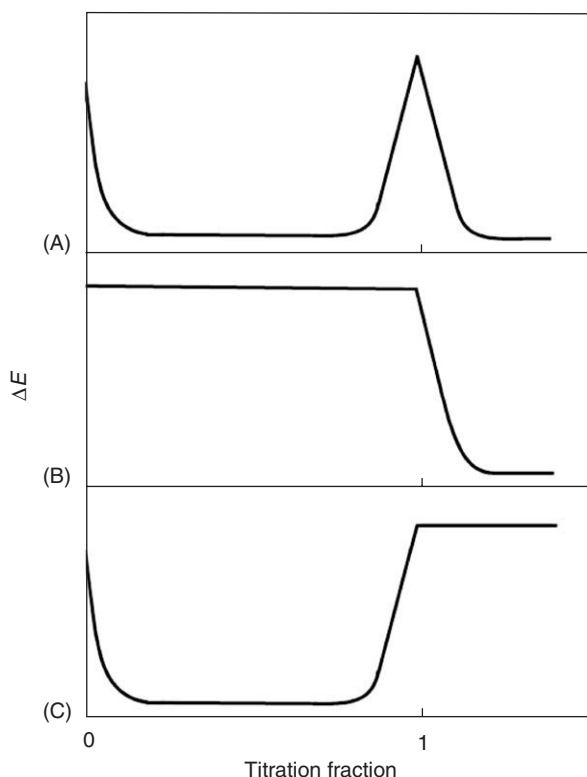

### Potentiometric Titrations with Polarized Indicator Electrodes

A number of oxidation–reduction systems (e.g., as  $\text{Cr}_2\text{O}_7^{2-}/\text{Cr}^{3+}$ ) are slow in establishing constant potentials at the platinum indicator electrode when measurements are made without current flow. It is possible to avoid long waiting times by forcing slight electrolysis to occur at the indicator electrode. Potentiometric titrations with polarized electrodes are divided in two classes, depending on whether one or two electrodes are used. In the former, the potential of a single polarized platinum indicator electrode against a reference electrode is measured. This indicator electrode may be polarized anodically or cathodically. If both couples involved in titration are reversible, the potential change of one polarized indicator electrode at the endpoint will be the same as when the electrode is not polarized. When one or both of the couples are irreversible, the potential change may be much greater in the case of a polarized electrode.

In the case of potentiometry with two polarized electrodes (bipotentiometry, or differential electrolytic potentiometry), the difference of potential between the two electrodes is measured. The shape of the titration curve depends on the reversibility of the couples involved in the titration. If both the titrant and the analyte are reversible couples (e.g.,  $\text{Fe}^{3+} + \text{Ce}^{4+}$  in  $\text{H}_2\text{SO}_4$ ), a curve with a maximum at the endpoint is obtained (Figure 4A). When the analyte forms an irreversible couple and is titrated with a reversible titrant couple (e.g.,  $\text{S}_2\text{O}_3^{2-} + \text{I}_2$ ) the potential decreases at the endpoint (Figure 4B). For the titration of a reversible analyte with an irreversible titrant another curve is obtained (Figure 4C).

### Automated Potentiometric Titrations

The most important component of an automated potentiometric titrator is the potentiometer. In simpler titrimeters, ordinary burettes are used to deliver the titrant and are equipped with automatic valves. Usually piston (syringe) burettes that allow delivery of the titrant with predetermined constant or variable speed are employed. Most automatic titrators have built-in electronic switches to perform various duties and include one or more derivatizing circuits enabling the location of the endpoint. The automated potentiometric titrators available in the market may be divided into four groups: (1) automatic titration curve recording instruments; (2) preset endpoint titrators, in which the flow of the titrant is stopped when the potential of the indicator electrode reaches a preselected value; (3) first- or

**Figure 4** Titration curves for potentiometric titration using two polarized electrodes: (A) analyte and titrant reversible systems; (B) irreversible analyte, reversible titrant; (C) reversible analyte, irreversible titrant.

second-derivative titrators that continue titration until  $dE/dV = \max$  or  $d^2E/dV^2 = 0$ ; and (4) automatic titrimetric analyzers, highly automated and suitable for routine analysis. These last instruments take a sample, dispense the solution, refill the burette, and rinse the cell and electrodes automatically. They also calculate the result and produce a printout or a graph.

Some automatic potentiometric titrators (continuous titrators) carry out the analysis continuously. The flow rate of the titrant varies according to the signal obtained from the electrode. Once a steady state has been attained, the flow rate of the titrant becomes the measure of the concentration of the analyte in the sample. If the potential of the indicator electrode and the flow rate of the titrant are recorded as function of time one obtains the record of the variation of analyte concentration with time.

Most automatic titrators can be utilized as pH-stats or potentiostats, with the purpose of maintaining the pH or redox potential of a solution at a given value.

Automatic potentiometric titrations are widely used nowadays in industrial and research laboratories. Most of the procedures used in normal titration need only slight alterations to make them suitable for automatic work.

Potentiometric endpoint detection is frequently used in automatic constant current coulometric titrators (coulometric titrations).

## Applications

Many different types of indicator electrodes can be used as endpoint indicators in potentiometric titrations. For example, an acid–base titration can be performed with a glass electrode as endpoint detector instead of using colored indicators, or chloride ions can be titrated with silver(I) using a chloride-ion- or silver-ion-selective electrode.

### Acid–Base Titrations

Acid–base potentiometric titrimetry will always play an important role in quantitative analysis because of the extremely large number of inorganic, organic, and biochemical compounds that possess acidic or basic properties. Potentiometric titrations of strong acids and bases with suitable strong titrants are relatively simple, since there is a relatively large and abrupt change in pH at the endpoint. As the acid (or base) titrated becomes weaker, the sharpness and magnitude of the endpoint decrease. A similar situation occurs when the concentration of the substance titrated (and the titrant) is decreased. If 0.1% accuracy is needed in titration of strong acid or base, the concentration of the substance titrated should be greater than  $\sim 3 \times 10^{-4} \text{ mol l}^{-1}$ , but if 1% accuracy is sufficient, the concentration can be decreased by one order of magnitude. For the titration of a weak acid with a strong base, the product of the acid concentration and its dissociation constant,  $K_a$ , should be greater than  $\sim 10^{-7}$  for 0.1% accuracy, or  $10^{-9}$  for 1% accuracy.

When the reaction equilibrium constants differ significantly (e.g.,  $\Delta pK > 4$ ) for comparable concentrations of two species, determination of both is possible from one titration run. As the reaction constants depend on the solvent properties, the change of solvent may be advantageous in subsequent titration of two analytes.

The range of applications of potentiometric titrations for determination of acids and bases is very wide, as illustrated by the following examples. Carbonate, hydrogencarbonate, and hydroxide ions are all bases that can be titrated with a strong acid such as hydrochloric acid. The most popular method for determination of nitrogen, which is found in many important substances such as proteins, fertilizers, drugs, pesticides, natural waters, is the Kjeldahl method, based on the conversion of the bound nitrogen to ammonia, which is then separated by distillation and determined by titration with hydrochloric

acid as the titrant. A large variety of esters can be determined by a potentiometric acid–base back-titration procedure, where an excess of potassium hydroxide added for saponification of the ester is determined. One very interesting acid–base titration is the determination of metal ions by the titration of hydrogen ions released by a complexation reaction.

The apparent acidity or basicity of a compound is strongly dependent on the solvent used. For example, phenol is too weak an acid for titration in aqueous solution. Very strong acids such as hydrochloric and perchloric acids cannot be titrated individually in water. However, such titrations can be performed successfully when appropriate nonaqueous solvents are used. Bases too weak to be titrated in water can be

titrated in protogenic solvents (solvents more acidic than water), for example, acetic acid. In this solvent, amines, medicinal sulfonamides, and most common alkaloids such as caffeine can be titrated with perchloric acid dissolved in the same solvent. Acids too weak to be titrated in water appear much stronger in protophilic solvents (solvents more basic than water). For example, ethylenediamine can be employed as a solvent for titration of phenols. Some solvents permit differentiation (or stepwise titration) of a series of acidic or basic species that, in water, titrate either together or not at all. This group of solvents includes dioxan, ketones, and hydrocarbons. For example, perchloric, hydrochloric, and acetic acids, and phenol, can be titrated in 4-methyl-2-pentanone solvent

**Table 1** Examples of acid–base titrations in nonaqueous solvents

<i>Solvent</i>	<i>Analyte</i>	<i>Titrant</i>
Methanol, ethanol	Inorganic and carboxylic acids	Cyclohexylamine in methanol or 2-propanol, CH <sub>3</sub> OK in methanol
2-Propanol	Carboxylic acids	(C <sub>4</sub> H <sub>9</sub> ) <sub>4</sub> NOH in 2-propanol
2-Methyl-2-propanol	Acid mixtures	(C <sub>4</sub> H <sub>9</sub> ) <sub>4</sub> NOH in 2-methyl-2-propanol
Acetic acid	Amines, aminoacids, salts, weak acids, sulfonamides	HClO <sub>4</sub> in dioxan or acetic acid
Dimethylformamide	Carboxylic acids, phenols, ammonium salts	CH <sub>3</sub> OK in methanol or benzene
Glycol + hydrocarbons	Salts of weak acids, amines	HClO <sub>4</sub> in dioxan
Benzene + methanol	Carboxylic acids, acid anhydrides	KOH in methanol, CH <sub>3</sub> OK in benzene + methanol
Ethylene diamine	Weak acids, phenols	(C <sub>4</sub> H <sub>9</sub> ) <sub>4</sub> NOH in 2-methyl-2-propanol
Acetonitrile	Amines, carboxylic acids	HClO <sub>4</sub> in dioxan, CH <sub>3</sub> OK in acetonitrile
Chloroform	Acids, alkaloids	C <sub>2</sub> H <sub>5</sub> ONa in ethanol, HClO <sub>4</sub> in acetic acid
Nitromethane	Acid amides, urea, amine oxides	HClO <sub>4</sub> in dioxan
4-Methyl-2-pentanone	Acids, acid mixtures	(C <sub>4</sub> H <sub>9</sub> ) <sub>4</sub> NOH in 2-propanol
	Heterocyclic amines	HClO <sub>4</sub> in dioxan

to obtain an endpoint for each compound, using tetrabutylammonium hydroxide in 2-propanol as titrant. Examples of acid–base titrations in nonaqueous solvents are given in Table 1.

### Precipitation Titrations

The potentiometric detection of the endpoint of precipitation titrations is very often used because not many visual indicators are available, in particular when mixtures of analytes are titrated. Halides, cyanide, sulfide, chromate, mercaptans, and thiols can be titrated with silver nitrate, using the silver sulfide-based ISE. Also complex mixtures, such as sulfide, thiocyanide, and chloride ions, or chloride, bromide, and iodide ions, can be titrated potentiometrically with silver(I) ions. When the solubility of a compound formed during titration is too high, nonaqueous or mixed solvents are used, for example,

when sulfates are titrated with lead(II) using a lead-ion-selective electrode. In this case water–ethanol solvent is used. Table 2 presents some examples of potentiometric precipitation titrations.

### Compleximetric Titrations

Many metal ions (e.g., calcium, cadmium, aluminum, lead) can be titrated with standard ethylenediaminetetraacetic acid (EDTA) or other compleximetric titrants, using an appropriate indicator electrode. When no direct appropriate indicator electrode exists, the addition of indicator metal ions can permit a determination. For example, barium may be titrated with EDTA in the presence of silver–EDTA complex as an indicator reagent using a silver electrode. Examples of compleximetric titrations are given in Table 3.

**Table 3** Examples of typical compleximetric titrations

Indicator electrode	Titrant	Analyte	Conditions
Ag	EDTA	$\text{Ba}^{2+}$ , $\text{Ca}^{2+}$ , $\text{Mg}^{2+}$	pH 9–10.5, in the presence of small amount of $\text{Ag}^+$
Ca-ISE	EDTA	$\text{Ca}^{2+}$	pH 10–12
Cu-ISE	EDTA	$\text{Cd}^{2+}$ , $\text{Co}^{2+}$ , $\text{Mn}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Pb}^{2+}$ , $\text{Zn}^{2+}$	pH 7–8
Cu-ISE	TETREN	$\text{Cu}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Zn}^{2+}$	pH 4–6, acetate buffer
Cu-ISE	$\text{CuSO}_4$	Chelating agents	pH 5–6

Hg	$\text{I}^-$	$\text{Hg}_2^{2+}$	
Pt	EDTA	$\text{Bi}^{3+}$ , $\text{In}^{3+}$ , $\text{Th}^{4+}$	0.2 mol l <sup>-1</sup> chloroacetic acid, in the presence of $\text{Fe}^{3+}/\text{Fe}^{2+}$
Pt	EDTA	$\text{Al}^{3+}$ , $\text{Cd}^{2+}$ , $\text{Cu}^{2+}$ , $\text{Ni}^{2+}$ , $\text{Pb}^{2+}$ , $\text{Zn}^{2+}$	Ammonium acetate, pH 5–6

TETREN, tetraethylenepentamine.

**Table 4** Typical potentiometric redox titrations of inorganic and organic compounds (in most cases a Pt electrode was used as the indicator electrode)

Analyte	Titrant	Conditions
$\text{As}^{3+}$	$\text{Ce}^{4+}$	4 mol l <sup>-1</sup> HCl, in the presence of ICl
$\text{C}_2\text{O}_4^{2-}$	$\text{MnO}_4^-$	0.2–1 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$ , 70°C
$\text{Ce}^{3+}$	$\text{MnO}_4^-$	1 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$
$\text{Co}^{2+}$	$\text{Fe}^{3+}$	Excess of 1,10-phenanthroline, pH 2–4
$\text{Cr}_2\text{O}_7^{2-}$	$\text{As}^{3+}$	20% $\text{H}_2\text{SO}_4$
$\text{H}_2\text{O}_2$	$\text{MnO}_4^-$	0.02 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$
$\text{I}^-$	$\text{MnO}_4^-$	0.1 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$
$\text{NO}_2^-$	$\text{Pb}(\text{CH}_3\text{COO})_4$	1 mol l <sup>-1</sup> NaCl
$\text{Ti}^{4+}$	$\text{Cr}^{2+}$	2 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$ , Hg electrode, absence of $\text{O}_2$
$\text{Ti}^+$	Chloramine T	3–4 mol l <sup>-1</sup> HCl, in presence of ICl
Aldehydes	$\text{KMnO}_4$	1.5 mol l <sup>-1</sup> $\text{H}_2\text{SO}_4$
Alkenes	$\text{Br}_2$ in $\text{CH}_3\text{COOH}$	In $\text{CH}_3\text{COOH}$
Amines	$\text{NaNO}_2$	Acidic solution
Ascorbic acid	$\text{Br}_2$ in $\text{CH}_3\text{COOH}$	In $\text{CH}_3\text{COOH}$
Carboxylic acids	$\text{KMnO}_4$	0.1 mol l <sup>-1</sup> NaOH
Cysteine	$\text{KIO}_4$	9 mol l <sup>-1</sup> HCl
Hydroquinone	$\text{Pb}(\text{CH}_3\text{COO})_4$ or $\text{Br}_2$ in $\text{CH}_3\text{COOH}$	$\text{Br}_2$ in $\text{CH}_3\text{COOH}$
Nitro-, Azo- comp.	$\text{Cr}(\text{CH}_3\text{COO})_2$	In $\text{CH}_3\text{COOH}$
Phenols	$\text{K}_2\text{Cr}_2\text{O}_7$	$\text{H}_2\text{SO}_4$
Quinone	$\text{Na}_2\text{S}_2\text{O}_3$	$\text{CH}_3\text{COOH} + \text{H}_2\text{O}$
Thiols	$\text{Pb}(\text{CH}_3\text{COO})_4$ or $\text{Br}_2$ in $\text{CH}_3\text{COOH}$	In $\text{CH}_3\text{COOH}$
Thiourea	Chloramine T	HCl + KBr

## Redox Titrations

Potentiometric titrations of oxidizing and reducing substances can be performed potentiometrically using inert electrodes, such as platinum or gold electrodes. Typical examples of applications include the titration of iron(II) ion with permanganate, titration of As(III) with bromine or iodine, and the determination of ascorbic acid with iodine. Many organic compounds such as azo, nitro, nitroso, carbonyl compounds, and quinones may also be determined. Because of their limited solubility in water those compounds are titrated in mixed or nonaqueous solvents. The Karl Fischer method of water determination based on the redox reaction between sulfur dioxide and iodine in the presence of a stoichiometric amount of water may be also mentioned. Water in liquid samples is titrated with titrant solutions containing iodine, sulfur dioxide, pyridine, and methanol as active solvent. Potentiometry, or more often bipotentiometry, is used for the detection of the endpoint of this titration. Some examples of potentiometric redox titrations are given in Table 4.

## Introduction

Titrimetry is a quantitative analytical technique which determines the volume of a solution of accurately known concentration that is required to react with the species being measured volume of the substance to be determined. The solution of accurately known strength is termed the titrant, and the substance being titrated is called the titrand.

For a reaction to be useful in titrimetry, the following conditions must be fulfilled:

1. The reaction must be simply explained by a chemical equation.
2. The reaction should be relatively fast.
3. There must be a change in the chemical or physical properties of the solution at the equivalence point (or end-point).

4. An indicator should be available that will identify the equivalence point of the titration (e.g., the indicator may undergo a color change or form a precipitation at the equivalence point).

However, there are instances when no visible indicator is available to identify the equivalence point of a titration. Also, some color changes can be very subtle, which can introduce subjectivity (and hence errors) in determining the equivalence point. In these situations, a more reliable detector than the human eye is required. In situations where the analyte, reagent, or titration product absorbs radiation, photometric measurements can be employed to determine the equivalence point of the titration.

## Principles

The end-point of a photometric titration is determined from absorbance measurements of the solution being analyzed. Beer's law for monochromatic light passing through a solution can be written as

$$A = \log(I_0/I) = \epsilon cl$$

## Redox Titrations

Potentiometric titrations of oxidizing and reducing substances can be performed potentiometrically using inert electrodes, such as platinum or gold electrodes. ## Introduction

Titrimetry is a quantitative analytical technique which determines the volume of a solution of accurately known concentration that is required to react with the species being measured volume of the substance to be determined. The solution of accurately known strength is termed the titrant, and the substance being titrated is called the titrand.

For a reaction to be useful in titrimetry, the following conditions must be fulfilled:

1. The reaction must be simply explained by a chemical equation.
2. The reaction should be relatively fast.
3. There must be a change in the chemical or physical properties of the solution at the equivalence point (or end-point).

4. An indicator should be available that will identify the equivalence point of the titration (e.g., the indicator may undergo a color change or form a precipitation at the equivalence point).

However, there are instances when no visible indicator is available to identify the equivalence point of a titration. Also, some color changes can be very subtle, which can introduce subjectivity (and hence errors) in determining the equivalence point. In these situations, a more reliable detector than the human eye is required. In situations where the analyte, reagent, or titration product absorbs radiation, photometric measurements can be employed to determine the equivalence point of the titration.

## Principles

The end-point of a photometric titration is determined from absorbance measurements of the solution being analyzed. Beer's law for monochromatic light passing through a solution can be written as

$$A = \log(I_0/I) = \epsilon cl$$

where  $A$  is the absorbance,  $I_0$  is the intensity of the incident light,  $I$  is the intensity of the transmitted light,  $\epsilon$  is the molar absorption coefficient,  $c$  is the concentration of the absorbing species, and  $l$  is the length of the light path through the absorbing medium. In photometric titrations, the path length,  $l$ , remains constant, and so the absorbance is directly proportional to the concentration of the absorbing species. The absorbance obtained at any point during the titration will be the sum of the absorbances of the titrant, titrand, and reaction product. As the end-point is reached, there should be a decreasing amount of titrand, an increasing amount of reaction product, and no titrant present in the titration vessel: therefore the absorbance is dependent on the absorption properties of the titrand and the reaction product. At the end-point of the titration, the concentration of the reaction product will have reached a maximum, and there should be no titrant or titrand present in the titration vessel, therefore the absorption at the end-point will be dependent on the optical properties of the reaction product. As more titrant is added once the end-point has been reached, any change in absorbance will be due solely on the absorption properties of the titrant as there should be no titrand present and the concentration of reaction product should remain constant. Therefore, in a titration in which the titrant, the titrand, or reaction product absorbs radiation, the plot of absorbance versus volume of titrant added will consist of two straight lines intersecting at the end-point (assuming that the volume change is small and the reaction goes to completion).

The shape of the curve obtained from a photometric titration is dependent on the optical properties of the titrant, reactant, and products of the reaction at the wavelength chosen for the measurement. Typical titration plots are shown in **Figure 1**. **Figure 1A** is typical of the curve obtained when a titrand that absorbs is converted into a product that does not absorb. The absorbance decreases as the amount of product increases and the amount of analyte decreases. However, after the end-point the product concentration remains constant, and therefore the absorbance measurement remains constant. **Figure 1B** shows the curve that would be obtained if the substance being titrated and the product were nonabsorbing and the titrant absorbs. The absorbance increases with excess titrant after the end-point. **Figure 1C** shows the curve that would be obtained where the product of the reaction absorbs, but both the titrant and the substance being titrated are non-absorbing. The absorbance increases with increasing product concentration, but after the end-point the product concentration is no longer rising, and so the

**Figure 1** Typical plots obtained from photometric titrations.

**Table 1** Selected examples of photometric titrations

Analyte	Titrant	Analytical wavelength (nm)	Corresponding graph in <b>Figure 1</b>
$\text{Fe}^{2+}$	$\text{K}_2\text{Cr}_2\text{O}_7$	335	B
$\text{Cu}^{2+}$	EDTA	745	C
2-Nitroaniline	$\text{HClO}_4$	464	A
$\text{I}^-$ (2nd end point)	$\text{Ce}^{4+}$	435	D

absorbance remains constant. Finally, **Figure 1D** is obtained when an absorbing titrant and an absorbing reactant produce a colorless product. The absorbance initially decreases as the analyte is consumed by the reaction, giving the nonabsorbing product. The absorbance reaches a minimum at the end-point and then increases due to the increasing amount of excess titrant, which absorbs. **Table 1** gives examples of photometric titrations that would exhibit titration curves similar to those shown in **Figure 1**.

In reality however, there is usually a small curvature at the end-point due to the reaction not going to full completion. This may be caused by the dissociation of reagents or products or the hydrolysis of weak acids or bases. The problem of curvature can be easily overcome by adding an excess of titrant and extrapolating from points remote from the end-point. It is also possible to improve the quality of the end-point determination by changing experimental parameters, e.g., pH and solvent/reagent concentrations. The best accuracy in determining an end-point of a photometric titration is when the extrapolated lines of the absorbance curve meet at an acute angle. Dilution effects caused by the addition of titrant must be corrected for. The absorbance values obtained are corrected by multiplying by  $(V_s + V_t)/V_s$ , where  $V_s$  is the volume of the sample and  $V_t$  is the volume of titrant added. If the correction for dilution effects is not carried out, the lines of the titration curve will bend towards the volume axis, resulting in an inaccurate determination of the volume of titrant added. To minimize dilution effects, a microsyringe can be used to add a relatively concentrated titrant to the sample being analyzed.

## Instrumentation

Photometric titrations can be carried out using a spectrophotometer that has been modified to permit the insertion of a titration vessel in the light path. However, it is much more common nowadays for photometric titrations to be carried out using automated apparatus consisting of a spectrophotometer or photometer, a titration vessel and stirrer, an automated burette, and software to control the titration and present the results. The titration vessels used are often cylindrical, with volumes of up to 100 ml. The titrant is incrementally added to the stirred vessel through the top and absorption readings taken after each titrant addition. Movements of the titration vessel during titrations must be avoided as inaccuracies will result due to deviations from Beer's Law. A diagram of a typical photometric titration cell is shown in **Figure 2**.

It is not essential to calibrate absorbance values to standards as the change in absorbance rather than the absolute absorbance is the important measure. This means that other species present that also absorb at the analytical wavelength or cause scattering of the light do not interfere with the end-point determination. However, interference can still occur if a species other than the analyte reacts with the titrant being used.

The accuracy and precision of photometric titrations are generally better than those obtained for direct absorbance measurements as the titration curve averages the data from a number of measurements. The relative precision of the end-point determination is typically around 0.5%. The accuracy is usually limited by the assumed concentration of the titrant, and therefore it is normal experimental procedure to titrate against a primary standard.

One of the major advantages of photometric titrations is the ease with which the sensitivity of the measurements can be changed simply by changing

the wavelength or the length of the cell path. When a titration reaction does not contain a self-indicating system, an indicator can be added in large amounts to provide a sufficient linear segment on the titration curve beyond the equivalence point.

## Applications

Photometric titrations are advantageous because the data from several measurements are used to determine the end-point, which results in a more accurate analysis. As only a change in absorbance is being measured, the presence of any other absorbing species will not interfere with the result obtained. Photometric titrations are popular for determining the amount of a metal ion in solution.

The concentration of copper(II) in a solution can be determined by titrating with ethylenediaminetetraacetic acid (EDTA). At a wavelength of 745 nm, the copper-EDTA complex has a much higher molar absorption coefficient than Cu(II), which means that a plot similar to **Figure 1C** would be obtained.

The concentration of iron(III) in solution can also be obtained by titration with EDTA. However, in this case salicylic acid is also added to the titration cell. Iron(III) forms a strongly colored complex with salicylic acid; however, the iron-EDTA complex has a much higher stability constant. As the titration is carried out, there is a very sharp disappearance of color at the end-point as the iron-EDTA complex replaces the iron-salicylic acid complex. This titration can be followed photometrically at 525 nm and produces a plot similar to **Figure 1A**.

Photometric titrimetry can be used for simultaneous determination of arsenic(III) and antimony(III) in a mixture. In acidic solutions, arsenic(III) can be oxidized to arsenic(V) and antimony(III) can be oxidized to antimony(V) by titration with a solution of potassium bromate and potassium bromide. The end-point of this titration can be observed by measuring the absorption at 326 nm. Initially, no change in the absorbance is observed until all the arsenic(III) has been oxidized to arsenic(V). The absorbance then decreases to a minimum at the end-point of the antimony titration, and then the absorbance increases again as excess titrant is added.

Similarly, the two end-points in the determination of *meta*- and *para*-nitrophenol can be determined by titrating with sodium hydroxide. This titration can be monitored by measuring the absorption of the phenoxide ion at 545 nm. The *para*-isomer is the stronger of the two acids and is neutralized first. There is a slight change in the slope from slightly positive gradient to a more positive gradient at this first end-point, followed by the absorbance

**Figure 2** A typical cylindrical titration vessel for use in photometric titrimetry.

remaining constant after the end-point of the *meta*-isomer neutralization. This titration would not be possible to follow using a visual indicator as the color change as the first end-point is too subtle.

Oxidizing agents such as permanganate and dichlorate absorb strongly in the visible region of the electromagnetic spectrum. This allows them to be used for photometric titrations. An example is the determination of iron(II) concentration by titrating with dichromate and measuring the absorbance at 335 nm.

Acid/base titrations can be monitored photometrically if a suitable indicator is added to the titration vessel. It is this indicator that causes the sharp change in the absorption profile at the end-point.

Photometric titrations have also been adapted for determining the end-point of precipitation titrations. The suspended solid produced by the titration reaction has the effect of reducing the energy of the radiation due to scattering, and so titrations can be carried out till a state of constant turbidity has been obtained.

## Introduction

Mycotoxins are fairly low relative-molecular-mass secondary metabolites of filamentous fungi that are toxic for humans and domesticated animals, causing economic losses by illness and death of animals when contaminated food or animal feed is consumed. There are many toxic metabolites produced by fungi, but only a fraction of these are currently considered to be important in foods. Similarly, a very broad

of the total volume. The acetone is left for 30 min to destroy any potentially harmful but reactive intermediates formed by the hypochlorite and then washed thoroughly. It is known, for example, that aflatoxin B1 can form a carcinogenic derivative if treated with hypochlorite alone.

A very detailed discussion of laboratory decontamination and destruction of aflatoxins in laboratory wastes has been prepared for the International Agency for Research on Cancer.

## Neurotoxins

**M-T Fernández-Sánchez, A Ferrero, A Pérez-Gómez, and A Novelli**, University of Oviedo, Oviedo, Spain

## Introduction

The term neurotoxin applies to a variety of substances that can affect the nervous system producing a broad variety of effects usually harmful to human health, although in some cases these substances can be of therapeutic use. Neurotoxic compounds are occasionally present in food and beverages, and consumption of contaminated products may therefore contribute to the etiology of certain psychiatric disorders or neurodegenerative diseases in humans. Three different main groups of

food-related neurotoxins may be considered: (1) metal and organometallic compounds (e.g., mercury and methylmercury, lead, cadmium, manganese, aluminum, and alkyltin); (2) marine and freshwater toxins of algal origin; and (3) toxicants purposefully added or resulting from industrial activities and accumulated in food including organophosphates and polychlorinated biphenyls (PCBs). In addition to food-related toxic compounds, poisons from venomous species may also contain potent neurotoxins. The analysis of metals and organometallic compounds as well as of organophosphates and PCBs are covered by other articles within the Encyclopedia. The following is a discussion of a variety of methods for the analysis and detection of different types of marine and freshwater neurotoxins of algal origin, and for some neurotoxic compounds from snake, scorpion, and spider venoms.

## Marine and Freshwater Toxins of Algal Origin

Algal toxins affect human health primarily through the consumption of seafood. Filter-feeding shellfish, zooplankton, and herbivorous fishes serve as vectors, either directly or through food web transfer, of sequestered toxins to higher trophic levels. According to their chemical structure and pathological effects, algal toxins have been classified into five major different groups, causing five different human seafood poisoning syndromes: paralytic shellfish poisoning (PSP), amnesic shellfish poisoning (ASP), ciguatera fish poisoning (CFP), neurotoxic shellfish poisoning (NSP), and diarrhetic shellfish poisoning (DSP). Toxins responsible for PSP, ASP, CFP, and NSP mediate their effects by diverse, highly specific interactions with ion channels involved in neurotransmission. DSP toxins are inhibitors of ser/thr protein phosphatases, critical components of signaling cascades in eukaryotic cells, including neurons. However, DSP toxins cannot be strictly referred as neurotoxins and will not be considered in this discussion.

In addition to seafood neurotoxins, we will also consider cyanobacterial toxins, which primarily impact on human health through drinking water contamination.

**Table 1** summarizes the biological activities of the main marine and freshwater algal neurotoxins, and the analytical methods most frequently used for their determination in shellfish tissue or algal extracts. The regulatory limit established for each toxin group is also indicated.

### Seafood Neurotoxins

The principal regulatory method to protect consumers from marine toxins in food is the mouse bioassay. It measures the time to death after intraperitoneal injection of a toxic extract, and toxicity is expressed as the amount of toxin (usually in micrograms) or toxin equivalents (eq) per gram (or 100 g) of shellfish tissue, standardized against a reference toxin solution. As it is a reliable indicator of human oral toxicity, the mouse bioassay is obligatory prior to commercialization of seafood in many countries. However, this biological test does not allow for specification of toxins or studies on the formation and effect of individual toxins. In addition, it has a high variability ( $\pm 20\%$ ) and low sensitivity, lacks specificity, and often has detection limits too near to the accepted threshold. Yet, the major limitation of the mouse bioassay is of ethical and political nature due to the use of live animals.

*In vitro* biological techniques are very promising approaches to detection of these phycotoxins in

extracts of shellfish tissues and toxic microalgae. Depending on the nature of the measured response, *in vitro* bioassays may be functional or nonfunctional. The latter category includes receptor binding assays and immunoassays, whereas the former includes activation/inhibition of enzymatic and cytotoxicity assays, all performed in live cells. Functional assays facilitate more information about the potential risk of a given sample because toxin analogs that may be not recognized by antibodies, or have too low receptor affinity to be detected by receptor-binding methods, may still be evaluated for their functional activity. Cytotoxicity assays using different cultured cell types have been developed in the last years. In particular, cultured neurons constitute a very suitable system because they are exquisitely sensitive to any compound that alters their physiological equilibrium, and allow any type of biochemical process activated by toxins to be monitored starting from steady-state conditions.

**Paralytic shellfish poisoning** PSP is the most widespread algae-derived shellfish poisoning. PSP toxins block voltage-dependent sodium channels, inhibiting nerve conduction and eventually leading to muscular paralysis and respiratory failure. The same mechanism is shared by a different toxin, tetrodotoxin, one of the most lethal seafood toxins, associated with the consumption of most pufferfish species. Chemically, PSP toxins are a group of alkaloid compounds collectively called saxitoxins (**Figure 1**).

Liquid chromatography (LC) is a powerful tool for the analysis of PSP toxins. These toxins have only a weak natural chromophore and must be modified prior to detection. The postcolumn reaction system is the usual method of choice, in which the effluent from the LC column is mixed with a chemical oxidant (periodic acid, pH 9.0), passed through a reaction coil, and acidified to form a fluorescent product. Oxidation can be also done electrochemically and, if a coulometric electrochemical detector is used, the oxidation results in a signal that can be used for the direct electrochemical detection of the toxins (ECD). However, this method requires long equilibration times to achieve steady background voltages and cannot be used with gradient elution profiles. Therefore, the use of direct ECD is limited to research laboratories working with relatively clean sample matrices.

To exclude inaccuracies, mainly due to interference between saxitoxin congeners, the use of two different LC methods is recommended. Positive findings should be confirmed by application of mass spectrometry (MS) but unfortunately, phosphate, ion-pair formers, as well as periodic acid from the

**Table 1** Summary of characteristics and methods for analytical detection of marine and freshwater neurotoxins of algal origin

<i>Toxin group and principal toxins</i>	<i>Pharmacology</i>	<i>Method</i>	<i>Approximate detection limit</i>
<b>PSP</b>			Regulatory Level: $0.8 \mu\text{g g}^{-1}$
Saxitoxins	Block of voltage-sensitive sodium channels	Mouse bioassay	$0.35 \mu\text{g g}^{-1}$
Gonyautoxins		Liquid chromatography Capillary electrophoresis Enzyme-linked immunosorbent assay Reverse cytotoxicity assay	$0.04 \mu\text{g g}^{-1}$ $0.5 \mu\text{g g}^{-1}$ $3 \text{ ng g}^{-1}$ $40 \text{ ng g}^{-1}$
<b>ASP</b>			Regulatory Level: $20 \mu\text{g g}^{-1}$

postcolumn derivatization unit often prevent an efficient application of the LC–MS coupling. An LC method has been developed that allows direct coupling of the liquid chromatograph with the mass

spectrometer. Separation of the PSP toxins was obtained on a weak cation-exchange resin using an aqueous eluent with ammonium acetate as the only additive. In the case of a parallel application of

LC-MS and fluorometric detection, electrochemical postcolumn derivation is suggested to avoid contamination of the ion source with chemical oxidation substances. This LC method is also well suited for the production of PSP standards from contaminated algae and mussels.

Capillary electrophoresis (CE) with ultraviolet detection is also a useful method for the separation and determination of PSP toxins. Separation conditions have been developed allowing the identification of products in crude enzymatic digestions using CE combined with tandem MS. However, CE separations demand highly purified extracts to obtain reproducible values and, also, the handling of very small volumes for injection results in limits of detection ~10 times higher compared to LC with fluorescence detection.

Total PSP toxicity after LC or CE separation must be calculated by summing up the individual concentrations of the respective PSP toxins quantified from

**Figure 2** Structure of domoic acid.

their corresponding peaks in the chromatograms. The values obtained by these chemical methods usually agree well with the results of the mouse bioassay.

Immunoassays, including radioimmunoassays (RIA) and enzyme-linked immunoabsorbent assay (ELISA), can be also used for the detection of saxitoxins. However, the presence of cross-reactions with lower binding specificity and the lack of response of all toxins within the saxitoxin family limit the use of these systems.

Based on the ability of PSP toxins to block sodium channels, a reverse toxicological assay has been proposed using cultured cerebellar neurons in which protection by saxitoxins from neurodegeneration induced by the sodium channel activator veratridine is measured. PSP content is calculated by comparison with known concentrations of purified saxitoxin, and values obtained with this method show very good correlation with values from LC and mouse bioassay.

**Amnesic shellfish poisoning** The main toxin associated with ASP is the tricarboxylic amino acid domoic acid (Figure 2), responsible for a human intoxication characterized by a widespread neurological dysfunction, chronic loss of memory, and motor neuropathy. The potent neurotoxic actions of domoic acid are due to the activation of a subtype (non-NMDA) of glutamate neurotransmitter receptors, and the subsequent depolarization leading to seizures and neuronal death.

Domoic acid can be analyzed semiquantitatively using thin-layer chromatography, which allows the analysis of multiple samples in a single run at relatively low cost, advantages particularly useful when applied to routine screening procedures of contaminated shellfish.

For quantitative purposes, the most common method is LC with ultraviolet detection, facilitated by the diene chromophore at 242 nm. When extreme sensitivity is required, ultraviolet absorbance is replaced by fluorescence detection of derivatized domoic acid. Prior to LC analysis, cleaning of sample is recommended. Usual cleaning procedures include aqueous methanol (1:1 v/v) extraction followed by a

solid-phase extraction or by passage of the supernatant through a strong anion-exchange column preconditioned with methanol, water, and extraction solvent. Effective separation can be accomplished using standard C18 analytical columns and isocratic elution. Acidic mobile phases are preferred, and in most cases a mixture of acetonitrile and water acidified with trichloroacetic or phosphoric acid is used.

Ion-spray LC-MS serves as an excellent confirmatory method for domoic acid. The positive-ion mass spectrum is characterized by an abundant protonated molecule ( $[M+H]^+$ ) at  $m/z$  312 with no significant fragmentation and, in order to achieve more structural information, tandem MS may be used to generate fragment ion spectra.

CE has been also successfully used for analysis of domoic acid and its isomers in seafood. For that purpose, crude homogenates should be previously cleaned-up using a strong anion-exchange column followed by a strong cation-exchange column, and then applied to a CE system interfaced to a variable wavelength ultraviolet detector operating at 242 nm. As mentioned for PSP toxins, the small injection volumes used makes the technique less sensitive than LC for shellfish samples. However, advances in technology such as the use of helium/cadmium laser in combination with CE to detect domoic acid that has been derivatized with dansyl chloride have led to unprecedented detection limits in the attomole ( $10^{-18}$  mol) range. Still, the major advantage of CE in routine applications remains the high degree of resolution for domoic acid and its isomers in a variety of shellfish homogenates.

A specific and sensitive direct cytotoxicity assay has been developed for domoic acid using cultured cerebellar neurons, consisting in the determination of neuronal death following 18–24 h exposure to domoic acid or analogs. Quantification is done using purified domoic acid as standard.

**Ciguatera fish poisoning and neurotoxic shellfish poisoning** CFP and NSP define two different syndromes caused by consumption of polyether compounds able to induce persistent activation of voltage-sensitive sodium channels. Interestingly, PSP toxins and tetrodotoxin (see above) antagonize the action of CFP and NSP toxins.

CFP is associated with the consumption of many species of tropical and subtropical fish contaminated by ciguatoxins, a family of lipid-soluble, heat-stable molecules (Figure 3) produced by the benthic dinoflagellate *Gambierdiscus toxicus*. Pacific ciguatoxin-1 (P-CTX-1) and Caribbean ciguatoxin-1 (C-CTX-1) are the major toxins contributing to CFP, and are usually considered the main

targets in any screening program. P-CTX-1 accumulates to levels between 0.1 and 5 ng g<sup>-1</sup> in the flesh of ciguateric fish. Based on a twofold risk factor, to secure public health it is necessary to reliably detect P-CTX-1 in fish flesh at 0.05 ng g<sup>-1</sup> and above. This is not possible using the mouse bioassay for P-CTX-1, which allows the detection of levels above 0.5 ng g<sup>-1</sup>. LC, MS, and LC-MS methods have been used to detect ciguatoxins in highly enriched extracts, but these approaches have insufficient sensitivity to detect clinically relevant toxin levels in crude extracts of fish. A robust gradient reverse-phase LC tandem MS method has been developed to determine CFP toxins using fish extracts spiked with pure P-CTX-1 or C-CTX-1 as internal standards.

Immunological detection of ciguatoxins and related polyethers has received particular attention compared to other marine toxins. The initial RIA and enzyme immunoassay employing a polyclonal sheep anti-ciguatoxin antibody revealed cross-reactivities between ciguatoxins and other polyether toxins, suggesting the need for monoclonal antibodies. The availability of monoclonal antibodies allowed for the development of stick enzyme immunoassay methods and solid-phase immunobead techniques (known as the paddle test), which successfully recognized toxins attached to correction fluid-coated bamboo sticks or paddles previously exposed to toxic fish tissues.

The toxins responsible for NSP are a group of at least 10 natural compounds known as brevetoxins (Figure 4), and produced by the unarmored marine dinoflagellate *Gymnodinium breve*. LC-MS methods have been proved successful for the analysis of brevetoxins in crude extracts of cultured *G. breve*. Indeed, LC-MS is a powerful technique that has been proposed as a 'universal' method for the analysis of most seafood toxins. Among advantages, LC-MS provides high selectivity and sensitivity, separation of complex mixtures, accurate quantitation, automation, legal acceptability for confirmation, and structural information for the identification of new toxins. As a drawback, costly equipment and operators with high level of expertise are required.

All brevetoxins can be detected by immunological techniques, including RIA as well as immunofluorescent tests and immunoabsorbant assays. The specific binding of brevetoxins and ciguatoxins at a particular site of the voltage-dependent sodium channel can be exploited and these receptors can be used in simple and effective receptor-based assays very much like antibody tests. The receptor assay works in membrane preparations, in microtiter plates, and in solubilized form, and can be done with tissue extracts or biological fluids as toxin source. The system should be also approachable by affinity techniques,

**Figure 3** Structure of ciguatoxins.

and it is expectable that derivatized toxins in radioactive, colorimetric, or fluorescent forms would be as useful as they are in immunological protocols. Since binding is the essential first step in the onset of toxicity, and more potent forms of the toxin bind more tightly to the receptor, the results obtained in receptor assays should properly reflect the toxicity of a sample.

Citotoxicity assays using murine neuroblastoma cells (Neuro-2A) have been proposed for the assessment of ciguatoxins and brevetoxins. The simplest method is based in the ability of metabolically active cells to reduce the tetrazolium compound MTT. After incubation with serial dilutions of test samples, cells are exposed to MTT and formation of color due to MTT reduction is read using a spectrophotometer. A new cytotoxicity assay is based on a c-fos-luciferase reporter gene that uses luciferase-catalyzed light generation as an endpoint and a microplate luminometer for quantification. After

incubation with toxins, cells are lysed and exposed to a mixture of luciferase and ATP, and the luminescence generated from each well is measured. Quantification of brevetoxins and ciguatoxins is done using known concentrations of the sodium channel activator veratridine as standard.

### Freshwater Neurotoxins

In freshwater, harmful algal blooms are mostly attributed to cyanobacteria, also known as blue-green algae. Cyanobacterial neurotoxins fall into three different categories: anatoxin-a and homoanatoxin-a, anatoxin-a(S), and saxitoxins (see **Figure 1** and **Figure 5** for chemical structures). As mentioned above, saxitoxins are produced by marine dinoflagellates and are known to concentrate in seafood and cause PSP in humans. Saxitoxins can be also found in cyanobacteria, where the presence of at least 19 different saxitoxins has been reported.

Type A(1) brevetoxins		Type B(2) brevetoxins

PbTx10	$\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{OH}$	PbTx3	$\text{CH}_2\text{C}(\text{=CH}_2)\text{CH}_2\text{OH}$
		PbTx5	[PbTx2], $\text{C}_{37}$ O-Acetate
		PbTx6	[PbTx2], $\text{C}_{27-28}$ Epoxide
		PbTx8	$\text{CH}_2\text{COCH}_2\text{Cl}$
		PbTx9	$\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{OH}$

**Figure 4** Chemical structure of brevetoxins.

**Figure 5** Chemical structure of anatoxins.

The development of analytical methods for anatoxin-a has been facilitated by the fact that the structure of this toxin was already solved in the late 1970s and chemical synthesis yielded the pure

compound to be used as a standard. Moreover, no variations of the chemical structure of anatoxin-a have been found except for the homoanatoxin-a and nonbioactive degradation products of both of these compounds. The method of choice now depends mainly on the amount of toxin contained in the samples to be analyzed, and the equipment available. Thin-layer chromatography has been used for purification of toxins and also as an inexpensive screening method. LC methods with ultraviolet or fluorimetric detection have been used to quantitate anatoxin-a, and several gas chromatography (GC) protocols using different derivatization procedures have been also used for anatoxin-a and homoanatoxin-a. The combination of LC or GC with MS has greatly improved the identification of these toxins and made it possible to look for the degradation products. In addition to MS, different nuclear magnetic resonance (NMR) techniques have been very useful for solving the unknown structures of cyanobacterial neurotoxins.

The same methods used for analysis of marine samples can be applied to saxitoxins originating from cyanobacteria. As already described, the most common methods to quantitate saxitoxins are based on LC with postcolumn derivatization and fluorimetric detection.

## Neurotoxins from Venomous Animals

Poisoning by venomous animals, particularly snakes, scorpions, and spiders, represents an important health problem, particularly in developing countries, where it has been estimated to cause more than 150 000 deaths per year. On the other hand, these venoms represent an incredible source of biologically active substances, extremely useful as research tools in a variety of biochemical and pharmacological studies. In particular, they contain peptides that are highly specific ligands for selected subtypes of ion channels, and that have been very useful to elucidate the structure and physiological roles of potassium, sodium, and calcium channels in a variety of cell types, including neurons.

**Table 2** summarizes the characteristics and the techniques usually employed for the analytical

detection of the main types of neurotoxins present in snake, scorpion, and spider venoms in body fluids.

### Snake Venoms

Snake venoms include toxins showing high selectivity for subtypes of muscarinic acetylcholine receptors, which control a variety of processes including the modulation of the heart rate, control of motor systems, and the modulation of learning and memory, as well as toxins that block particular subtypes of voltage-dependent sodium or potassium channels in neurons.

Detection of snake toxins and toxin antibodies in body fluids remains very important for the identification of the biting species and the correct management of envenomation. As snake venoms consist of a complex mixture of pharmacologically active peptides and proteins, detection is usually approached by immunological techniques. Radioimmunoassay (RIA) using specific monoclonal antibodies has proved to be highly reliable and sensitive. However, the difficulty of handling radioisotopes and the need of elaborate equipment limit its application in

**Table 2** Biological activity and detection methods for neurotoxins from venomous animals

<i>Neurotoxin source and principal toxins</i>	<i>Pharmacology</i>	<i>Method</i>	<i>Approximate detection limit</i>

routine diagnosis in the field. In contrast, agglutination tests using purified rabbit antivenom IgG are inexpensive, rapid, and simple to perform, making them appropriate for use in rural health centers of developing countries, but because of low level sensitivity and instability of the coupling agents, these tests have received only limited attention. In terms of specificity, sensitivity, rapidity, and simplicity, ELISA methods appear to be the ideal systems for detecting venom and venom antibodies. Approaches to achieve species specificity have included the use of a single venom component as the immunogen and the use of mixtures of monoclonal antibodies or affinity purified venom-specific antibodies as immunoreagents. The incorporation of avidin–biotin system and fluorogenic substrates significantly increased the sensitivity of these techniques allowing the detection of venom concentrations at picogram levels. Since snakebite is a medical emergency, immediate identification of the species is needed in order to administer the specific antivenom. In this respect, optimization of ELISA with unprocessed and undiluted blood and other biological samples reduced the assay time considerably. Optimization of the incubation steps at ambient temperature and visual discrimination of the optical density of test samples compared to controls are the two main approaches followed to achieve simplicity. Only a few commercial detection kits have been developed. Among them, a highly sensitive species-specific avidin–biotin microtiter ELISA (AB-microELISA) kit for the detection of venoms from four common Indian snakes has demonstrated efficacy to detect venom levels up to  $10 \text{ ng ml}^{-1}$  without ambiguity. The assay can be performed using  $600 \mu\text{l}$  of blood collected with an anticoagulant without further manipulation and can be completed in 30 min. Recently, an ion-sensitive field effect transistor based immunosensor has been developed for the detection and quantification of the potent neurotoxin  $\beta$ -bungarotoxin. For analysis, separation, or structural studies of these toxins at the basic research level, a variety of methods have been used including LC, LC–MS, CE, MS, and NMR.

### Scorpion Venoms

Scorpion envenoming remains a serious public health problem in certain regions, causing a considerable number of fatalities especially among children. Venoms contain many small proteins specifically interacting with ionic channels in excitable membranes. The main targets are voltage-sensitive sodium channels, although there is also a big family of peptides mostly active on potassium or chlorine

channels. The usual therapy includes the application of antivenom to neutralize circulating toxins. In order to administer the adequate amount of antivenom, it is important to do a rapid quantification of the circulating toxin concentration and to establish a correlation between the concentration of venom, the clinical symptoms, and the severity of the envenoming. Similarly to snake venoms, ELISA methods are very suitable for scorpion neurotoxin analysis. For example, a sandwich-type ELISA has been developed for the identification of circulating toxic antigens from *Tityus serrulatus* from Brazil, using the toxic fraction from the scorpion venom purified by Sephadex G-50 chromatography, and specific antibodies identified by immunoaffinity techniques to react to that fraction. The assay was specific for *T. serrulatus* venom, but because of its low sensitivity ( $4.8 \text{ ng ml}^{-1}$ ) it failed to distinguish between patients with mild envenoming and the nonenvenomed control group. A more sensitive sandwich-type ELISA test has been reported for the quantification of toxic fraction from North African scorpion venoms in human serum. The test proved to be reproducible, and its high sensitivity (detection limit of  $0.9 \text{ ng ml}^{-1}$ ) allowed for an accurate determination of scorpion venom concentration in human sera even at low levels.

### Spider Venoms

Most spider neurotoxins characterized to date have been found to be low molecular weight organic molecules (inorganic ions and salts, free acids and aminoacids, biogenic amines, neurotransmitters, and acylpolyamines), peptides, or proteins. Polyamines and a variety of polypeptides with a molecular mass ranging from 3000 to 8000 Da appear to represent the main toxic compounds in spiders. More than 60 peptide toxins have been described to date, whose presence can be confirmed by reversed-phase LC. Peptides can be easily distinguished from polyamines because of their different retention times and by ultraviolet detection using a diode-array detector.

The search for novel pharmacological tools in spider venoms requires precise and reproducible methods for the identification of species. Reversed-phase LC and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS) analysis of crude venoms offers a powerful systematic tool that, in combination with morphological methods, has been used successfully to discriminate among closely related tarantula species. The method allows for the precise, sensitive, and rapid mass fingerprinting of large numbers of

samples in a reproducible manner. In most cases, the concomitant presence of peptides and polyamines has been detected, although with an overall predominance of peptides as toxic constituents. LC-MS may be also used as an additional venom characterization tool. When applied to the study of several tarantula venom samples, both MALDI-TOF-MS and electrospray ionization MS gave similar overall profiles and allowed fine discrimination of samples. In those studies, coupling of MS with LC allowed for clear discrimination between components of similar molecular weight and provided relevant information about venom composition, number of molecular species, and molecular weight distribution.

Spider venoms may also contain high molecular weight neurotoxic proteins. For example, in the genus *Latrodectus* (black widow) the high neurotoxicity of the venom is caused by a family of 110 kDa proteins called latrotoxins, which induce massive neurotransmitter release. Latrotoxins may be purified to homogeneity using chromatographic techniques and testing for the ability of fractions to deplete nerve terminals of their acetylcholine quantal store and of synaptic vesicles. Electrophoretic techniques may be also a convenient approach for the separation and characterization of venom components. Several proteins from the spider *Selenocosmia huwena* have been identified using two-dimensional gel electrophoresis, with the separation in the first dimension on a wide range of immobilized pH gradients. Proteins were then electrotransferred to a poly(vinylidene difluoride) membrane and analyzed by N-terminal microsequencing and MS peptide mapping.

Specific antigens in the sera of envenomed patients can be detected using ELISA analysis provided that purified specific antibodies are available. Thus, a highly specific sandwich-ELISA has been developed using affinity chromatography purified horse anti-*P. Nigriventer* immunoglobulins. Also, a sensitive ELISA has been developed for the specific detection of *Loxosceles* species venom.

remaining constant after the end-point of the *meta*-isomer neutralization. This titration would not be possible to follow using a visual indicator as the color change as the first end-point is too subtle.

Oxidizing agents such as permanganate and dichlorate absorb strongly in the visible region of the electromagnetic spectrum. This allows them to be used for photometric titrations. An example is the determination of iron(II) concentration by titrating with dichromate and measuring the absorbance at 335 nm.

Acid/base titrations can be monitored photometrically if a suitable indicator is added to the titration vessel. It is this indicator that causes the sharp change in the absorption profile at the end-point.

Photometric titrations have also been adapted for determining the end-point of precipitation titrations. The suspended solid produced by the titration reaction has the effect of reducing the energy of the radiation due to scattering, and so titrations can be carried out till a state of constant turbidity has been obtained.

### Introduction

Mycotoxins are fairly low relative-molecular-mass secondary metabolites of filamentous fungi that are toxic for humans and domesticated animals, causing economic losses by illness and death of animals when contaminated food or animal feed is consumed. There are many toxic metabolites produced by fungi, but only a fraction of these are currently considered to be important in foods. Similarly, a very broad

range of fungal species may produce toxic metabolites, but in human food the most important genera are *Aspergillus*, *Penicillium*, and *Fusarium*. Although the presence of a mycotoxin in a food usually implies previous infection by, and growth of, the mold producing the mycotoxin on the food, or a constituent of the food, there are two significant instances when that is not so. Thus aflatoxin M1 is secreted into milk following consumption by a cow of feed contaminated by aflatoxin B1. Ochratoxin A can pass unmetabolized into the kidney and muscle tissue of the pig after feeding on a contaminated feed such as barley.

Toxicogenic fungi (i.e., those able to produce mycotoxins) are hardly ever detectable in (cooked) food or feed. Indeed, in most cases, the fungi have disappeared when mycotoxins, which are very stable molecules due to their chemical structures, are found in food. If still present, mycological analysis based on the taxonomic characteristics of the fungi strains provide some indications but cannot be used to draw conclusions on the occurrence of toxins on food. In fact, mycotoxins are more resistant than the micromycetes that synthesized them, and a treatment as simple as heating can greatly diminish the number of revivable germs without modifying the toxicity.

More than 350 mycotoxins have been identified either from food or from laboratory culture media. The main mycotoxins (Table 1) of concern for the safety of consumers are aflatoxins (aflatoxins B and G, aflatoxin M1), ochratoxin A, patulin, fumonisins, zearalenone, and deoxynivalenol (DON) and other

*Fusarium* toxins, also called trichothecenes. Other mycotoxins are also encountered but to a lesser extent, and consecutively they are of less concern for public authorities: cyclotriazonic acid, sterigmatocystin, penitrem A, and tenuazonic acid. The structures of these mycotoxins are shown in Figures 1–10.

## Toxicity of Mycotoxins and Regulations Regarding Mycotoxins in Food

Mycotoxins are highly toxic for human beings and for animals. For instance, aflatoxins, especially aflatoxin B1, are highly hepatotoxic and indicated as potent carcinogens. Ochratoxin A is responsible for nephrotoxicity, and it is suspected of playing a role in the well known Balkan endemic nephropathy, where the incidence of tumors of the bladder or urinary tract is significantly higher than in the healthy population. Fumonisin has been identified as the causative agents for several animal syndromes like equine leucoencephalomalacia, a fatal syndrome in horses consisting of liquefactive necrosis in one or both cerebral hemispheres leading to extensive and fatal damage to tissue brain. Besides, fumonisin B1 may be involved in esophageal cancer as its involvement was suspected in some regions of China and South Africa. DON is also called vomitoxin as it causes food refusal in animals; there is also some evidence of its immunotoxicity effects. Zearalenone has estrogenic effects and is known to produce hyperestrogenism in pigs.

**Table 1** Mycotoxins found in food

Mycotoxin	Figure	Food	Common fungi species producing the mycotoxin
Aflatoxins B1, B2, G1, G2	1	Groundnuts, peanuts, tree nuts, shell-fruits (pistachios, nuts), maize, figs, dried raisins, spices	<i>Aspergillus flavus</i>
Aflatoxin M1	1	Milk and milk products (cheese)	<i>A. parasiticus</i> Metabolite of aflatoxin B1 transferred into milk
Cyclotriazonic acid	2	Cheese (crust), maize, groundnuts, millet	<i>Aspergillus flavus</i> <i>Penicillium aurantiogriseum</i>
DON	3	Cereals (wheat)	<i>Fusarium graminearum</i> <i>F. culmorum</i>
Fumonisin	4	Maize	<i>Fusarium moniliforme</i>
Ochratoxin A	5	Cereals (barley, oats), maize, coffee and cacao beans, raisins and wine, beer, pork-derived products (offal)	<i>Penicillium verrucosum</i>
Patulin	6	Apple, apple juice, and puree	<i>Aspergillus ochraceus</i> <i>A. carbonarius</i> <i>Penicillium expansum</i>
Penitrem A	7	Walnuts	<i>Penicillium aurantiogriseum</i>
Sterigmatocystin	8	Cereals, coffee beans, cheese	<i>Aspergillus versicolor</i>
Tenuazonic acid	9	Tomato paste	<i>Alternaria tenuis</i>
Zearalenone	10	Maize, barley, wheat	<i>Fusarium graminearum</i>

**Figure 1** Aflatoxins B1, B2, G1, G2, and M1.

**Figure 2** Cyclopiazonic acid.

**Figure 3** Deoxynivalenol.

Recognition of the importance of those mycotoxins in public health is reflected in the issuing of statutory and advisory regulations for the maximum tolerable levels in food and animal feed in many countries. The

presence of some mycotoxin molecules has been regulated by public authorities to guarantee food safety for populations (Table 2). A lot of countries have individually enforced regulations for mycotoxins in food and feed, especially for aflatoxins. Many countries have especially stringent levels for aflatoxin M1 in milk and dairy products, ranging from 0.01  $\mu\text{g}$  per kg in pasteurized fresh milk for infants in Austria to 0.5  $\mu\text{g}$  per kg for milk and milk products in the USA. This clearly reflects the major concern regarding exposure of very young and elderly people, who would be more likely to be both more sensitive and exposed to higher levels of toxins.

In the European Union and in the America block, uniform regulations have been put in place. The Codex Alimentarius is also attempting a worldwide uniformity in recommending the maximal tolerable limits for the main mycotoxins of concern (aflatoxins, ochratoxin A, fumonisins, patulin, DON, zearalenone); the Codex Alimentarius is also supervising the writing of codes of practice for farmers to help prevent the production of mycotoxins in crops as the

**Figure 4** Fumonisin B1.**Figure 5** Ochratoxin A.**Figure 8** Sterigmatocystin.**Figure 6** Patulin.**Figure 9** Tenuazonic acid.**Figure 7** Penitrem A.**Figure 10** Zearalenone.

US Department of Agriculture (USDA)/Food and Drug Agency (FDA) have already done.

Many countries have implemented official controls and national monitoring programs to survey food and feed contamination. Also, international trade requires the control of consignments susceptible to contamination by mycotoxins. Due to the carcinogenic potency of most mycotoxins, they should be tracked at trace levels in food, 'trace' referring mainly to the parts per billion level (i.e., micrograms per kilogram). Besides, the diversity of the chemical structures of mycotoxins and the wide range of foods and animal feeds are the main hindrance for developing one single method for many mycotoxins from

any consignment, but it has been achieved for one matrix, namely beer. The establishment and use of agreed analytical methods development are needed to ensure the reliability of analytical data, especially in case of dispute. Nowadays, methods are required by officials to be validated by collaborative studies (i.e., by interlaboratory study) or at least to be in-house validated. For that purpose, international standards like ISO 5725, 1998 or the uniform International Union of Pure and Applied Chemistry–Association of the Official Analytical Chemists (AOAC) protocol for validation of methods by a single laboratory are available that are totally suitable for validation of methods for the determination of mycotoxins in food.

**Table 2** Maximum tolerable limits for mycotoxins: some examples (for more information on worldwide regulations, see [www.fao.org](http://www.fao.org))

<i>Mycotoxins</i>	<i>Maximum tolerable limits (in food as consumed) (<math>\mu\text{g per kg}</math>)</i>	<i>Sources</i>
Aflatoxins B1 (and sum of aflatoxins B and G) in peanuts, nuts, dried fruits, and cereals	2 (4)	European Commission
Aflatoxins B1 (and sum of aflatoxins B and G) in spices	5 (10)	European Commission
Aflatoxin M1 in milk	0.05	European Commission
Ochratoxin A in cereals	0.5	US-FDA and Codex Alimentarius

## Sampling

Before an analysis can be attempted, a sample must be obtained. The analyst is frequently presented with a single sample, adequate in quantity for the analytical methodology but without any guarantee that it is representative of the consignment of food or animal feed from which it came. Many commodities to be analyzed are particulate in structure, and molds do not grow uniformly through such materials. Thus, mycotoxins are not usually distributed evenly throughout a consignment, although exceptions may be mycotoxins in fluids like aflatoxin in milk or patulin in fruit juice, and it is important to agree on a sampling plan that adequately protects the consumer without unnecessarily penalizing the producer. There is not even a normal distribution of mycotoxins within a batch of a commodity. For example, in the contamination of groundnuts, maize, cotton seed, or palm kernels with aflatoxins, it is likely that a relatively small number of kernels or seeds are contaminated with very high levels and many are not contaminated at all, giving a very skewed distribution.

Satisfactory sampling plans, such as those devised for groundnuts by the USDA, the Natural Resources Institute of the UK, or the European Commission should define the size of the sample and how it is to be collected, a method for dividing the sample, and an analytical procedure. The USDA sampling plan for the determination of aflatoxins in groundnuts requires 66 kg of material be collected from at least 100 sacks for each 20 tonne lot. The 66 kg is divided into three subsamples of 22 kg, and the first one of these is grounded, thoroughly mixed, and analyzed. At a time when the maximum tolerated level was 25  $\mu\text{g per kg}$ , if the result of this first analysis was less than 16  $\mu\text{g per kg}$  the lot was accepted and if it was greater than 75  $\mu\text{g per kg}$  it was rejected. If, however,

the first analysis gave a result between these two figures, then a second subsample had to be analyzed in the same way. If the mean of the two was less than 22  $\mu\text{g per kg}$  the lot was accepted and if greater than 38  $\mu\text{g per kg}$  rejected, but again if the result fell between these two figures then the third subsample had to be analyzed. In this example, the mean of all three now needs to be less than or equal to 25  $\mu\text{g per kg}$  for the lot to be accepted.

For many years, sampling was not taken sufficiently seriously, but detailed research on the distribution of mycotoxins in commodities and an appropriate statistical analysis of the results have led to an increased use of acceptable sampling plans. Recognition of the extremely skewed distribution of mycotoxins has also led to the design of methods for recognizing and eliminating the heavily contaminated kernels from consignments, thus ensuring that they do not contribute to the overall contamination of the batch after further treatment such as mixing, grinding, and oil extraction.

## Methodology for Analyzing Mycotoxins in Food

The main difficulties in the analysis of mycotoxins are due to the fact that they should be detected at very low levels (micrograms per kilogram, sometimes at nanogram per kilogram levels) in very complex food matrices. Most mycotoxins (except DON or zearalenone) are not sufficiently UV absorbing to be detected as traces using an UV detector. Hopefully, most of them are fluorescent by themselves or after having a fluorophore coupled to them. This is the case for aflatoxins whose fluorescence is strongly enhanced by iodination or bromination of the mobile phase used in liquid chromatographic systems, where

under an elevated temperature, iodine or bromine is generated and coupled to the aflatoxin, resulting in high emission of fluorescence. Less corrosive reagents such as cyclodextrins have also been demonstrated to be efficient in enhancing the fluorescence of aflatoxins.

Methods of analysis for mycotoxins mainly include four steps: (1) grinding the sample of food, (2) extracting the mycotoxin using organic solvents or aqueous solvents, sometimes using water, and concentrating the extract, (3) purifying the extract using silica-like cartridges or immunoaffinity columns, and (4) analysis using chromatographic techniques or immunochemical techniques like enzyme-linked immunosorbent assay (ELISA); often, in the case of ELISA techniques, the preparation of samples is easily simplified to the two first steps.

### Extraction Procedures and Purification of Mycotoxins before Analysis

Cleanup procedures vary considerably, depending on both the mycotoxin(s) and the commodity to be analyzed. Although mycotoxins are readily soluble in water-organic solvents, it is not always easy to remove them from the macromolecular food matrix by direct extraction with simple solvents such as chloroform, ethyl acetate, aqueous solvents, or water (as in the case for DON). However chloroform, although one the most efficient solvents for extracting most mycotoxins, is being recommended less frequently because it is an ozone-depleting agent: it has mainly been replaced by acetonitrile, methanol, or a combination of these aqueous solvents. For some

fatty matrices, it may be necessary to remove oils and fats through a preliminary extraction with hexane before extracting the mycotoxin. Some mycotoxins (aflatoxins, ochratoxin A, patulin, etc.) can be adsorbed onto C8 or C18-silica cartridges and/or Florisil<sup>TM</sup> (commercially available) and subsequently eluted. Fumonisin are better extracted using strong anion exchange columns.

Nowadays, the application of immunoaffinity chromatography to mycotoxins has considerably improved the extraction and purification of mycotoxins from a large range of food matrices. Consecutively the recovery and the limit of detection of the methods have been strongly improved. The principle of immunoaffinity chromatography is as follows (**Figure 11**): monoclonal antibodies specifically produced against a mycotoxin are immobilized onto an inert support and packed in a microcolumn (support of 1 cm height or so). The food extract, rediluted in water or phosphate buffered saline-like buffer to be neutral at around pH 7, is passed through the column. When most of the constituents of the extract are washed out of the column, the mycotoxin molecules are specifically retained to the antibodies. Because the mycotoxins are not covalently bound to antibodies, they can be displaced by an organic solvent like methanol or acetonitrile and eluted as a highly pure concentrated extract that could then be analyzed using chromatographic methods. Now, numerous brands of immunoaffinity columns are commercially available for the main mycotoxins analyzed. This method of food extract purification has become increasingly popular despite the price of immunoaffinity columns remaining high. This procedure is now included in most recently validated methods earlier than liquid chromatographic methods.

**Figure 11** Principle of immunoaffinity chromatography.

## Chromatographic Methods

Chromatographic methods used with mycotoxins include thin layer chromatography (TLC), liquid chromatography (LC), gas chromatography (GC), and LC coupled to mass spectrometry (LC-MS).

### TLC Methods

TLC methods were very popular several decades ago when they were used in the discovery of mycotoxins or for the analysis of less known mycotoxins, especially when no standards were available. TLC methods were gradually replaced by LC except in laboratories of developing countries not equipped with LC. TLC is also much cheaper than LC due to the price of the LC apparatus and the cost of the solvents. These methods are also used in analyzing multicontaminated samples (i.e., contaminated by several mycotoxins), which is not possible using LC in that case several kinds of mobile phases are required.

Some mycotoxins (especially aflatoxins) are able to fluoresce under long-wave UV (360 nm) when absorbed on a solid substrate such as the silica gel of a TLC plate. For instance, aflatoxins were divided into two groups, named B and G, after the bluish and greenish fluorescence they produce. The main problem experienced with years of analysis of aflatoxins is that many natural products fluoresce blue or green under UV and many of these compounds have an  $R_F$  value close to, or even identical with, that of one of the four common aflatoxins. These false-positive results need to be confirmed, which could be done by applying to the extract a two-dimensional TLC coupled with the derivatization specific to the mycotoxins. One of these protocols for confirming the presence of aflatoxins uses trifluoroacetic acid to derivatize as hemiacetals the aflatoxins B1 and G1.

The AOAC standardized a lot of procedures based on TLC that were validated by collaborative studies and met the AOAC requirements regarding performance criteria. The AOAC standards provide detailed information on the apparatus, the reagents, the preparation of standards, and the sampling. A selection of these methods and the most recent ones are quoted in the standard procedures section.

### LC Methods

LC methods are now the procedures of choice in the mycotoxin field. Many LC methods have also been collaboratively validated and published as standards (AOAC official methods or ISO standards or EN standards). When standard solutions of mycotoxins are commercially available, any good LC laboratory could implement those kinds of methods; moreover, due to the use of a fluorescence detector, very small

traces can be detected with very good reproducibility. Another major advantage of LC is the possibility of automation and the use of autosamplers, allowing unattended operation of LC equipment. Online cleanup of crude extracts and online derivatization before or after separation are additional advantages. A range of detectors can be used, although the most widespread are based on UV absorption (patulin, zearalenone) or detection of fluorescence (for most mycotoxins), the latter being potentially 30–40 times more sensitive, as has been demonstrated for aflatoxins.

Well-established and interlaboratory validated LC methods are published in the scientific specialized literature or as international standards. Those approved by the AOAC are mentioned in the standard procedures section (see also [www.mycotoxins.org](http://www.mycotoxins.org) for a complete list of references). Their main features are described in Table 3. Most of these protocols include the use of immunoaffinity columns before LC analysis.

### GC Methods

For GC the mycotoxins need to be sufficiently thermostable and volatile or be converted into volatile derivatives. The two most widely used detectors in mycotoxin analysis – flame ionization detectors (FIDs) and electron capture detectors (ECDs) – do not require that a compound show any fluorescence or UV absorption, and the group of mycotoxins for which GC was initially the most widely used was that of the trichothecenes. More recently another group of *Fusarium* mycotoxins, the fumonisins, which also lack the appropriate optical properties, have been analyzed successfully using GC.

Many mycotoxins, including the trichothecenes and fumonisins, have polar hydroxyl groups that can be readily derivatized to trimethylsilyl ethers with such reagents as trimethylsilyl chloride or hexamethyldisilazane and *N*-trimethylsilylimidazole. Alternatively polyhalogenated acyl derivatives can be made, using reagents such as trichloroacetic anhydride or heptafluorobutyric anhydride, which are especially useful in conjunction with ECDs.

There is a large number of different trichothecenes, and ideally their analysis requires confirmation using MS coupled to GC (GC-MS) and analysis of the macrocyclic trichothecenes, which include verrucarins, roridins, and satratoxins, requires considerable experience and a specialized laboratory. However, well-established methods are available for individual trichothecenes of particular importance, such as the T-2 toxin, diacetoxyscirpenol, DON, and neosolaniol. The large number of *Fusarium* trichothecenes are acylated derivatives of a much smaller number of parent alcohols, such as T-2 tetraol,

**Table 3** Some examples of the analytical protocols of collaboratively validated LC methods for mycotoxins

<i>Mycotoxins and matrices</i>	<i>Extraction solution</i>	<i>LC method and detection</i>	<i>Limits of quantification</i>	<i>Recovery (%)</i>
Aflatoxins B and G in peanut butter, pistachios, fig paste, and paprika	Methanol 80% and defatting with pure hexane	Immunoaffinity cleanup prior to LC coupled to fluorescence detector and postcolumn derivatization by using iodination or bromination	0.2 µg per kg of aflatoxin B1  0.4 µg per kg for sum of aflatoxins B and G	85–100
Aflatoxin M1 in milk	No previous extraction	Immunoaffinity prior to LC coupled to fluorescence detector	0.005 µg l <sup>-1</sup>	70–95
Ochratoxin A in barley	Acetonitrile 60%	Immunoaffinity prior to LC coupled to fluorescence detector	0.6 µg kg <sup>-1</sup>	65–110
Ochratoxin A in roasted coffee	Methanol/sodium bicarbonate followed by chromatography on phenylsilane cartridge	Immunoaffinity prior to LC coupled to fluorescence detector	0.3 µg kg <sup>-1</sup>	65–97
Patulin in apple juice and puree	Ethylacetate	LC coupled to UV detector	15 µg kg <sup>-1</sup>	70–100
	Pectinase treatment for puree	LC coupled to UV detector		
Fumonisin in corn and cornflakes	Acetonitrile/methanol/water	Immunoaffinity prior to LC coupled to fluorescence detector	0.4 µg kg <sup>-1</sup>	75–110
DON in wheat	Water	Immunoaffinity prior to LC coupled to UV detector	100 µg kg <sup>-1</sup>	> 80

scirpentriol, DON, and nivalenol, and so another approach to their analysis is to hydrolyze the possibly complex mixture of trichothecenes to the parent alcohols and analyze these as their trimethylsilyl ethers. However, when this is done, there is often a poor correlation between the total trichothecene content and the observed toxicity, reflecting the large differences in the toxicity of different acyl derivatives even of the same parent alcohol.

As for patulin, it is necessary to derivatize it with trimethylsilyl ether or heptafluorobutyrate to make it volatile. Determination of patulin through GC–MS detection and quantification of the heptafluorobutyrate derivative after treatment with heptafluorobutyrylimidazole has also been developed. Trimethylsilyl can also serve as a derivatization agent for the detection of patulin through GC–ECD or GC–MS. However, it should be noted that LC methods are generally preferred over GC methods because of their easiness of application.

### LC–MS Methods

LC–MS is one of the most advanced techniques available for the detection of mycotoxins. They are

especially used for confirmatory purposes; they have very recently become the method of choice for trichothecenes, gradually replacing GC–MS methods, which appear less reliable. Extraction and cleanup techniques have to be applied prior to separation and detection in order to enable well-separated peaks without interferences from matrix components. In brief, the LC effluent enters an ionization chamber via a nebulizer. Ionization is performed through several techniques (electrospray, thermospray, chemical, fast atom bombardment, etc.). In a collision chamber fragmentation takes place and fragments then enter the high-vacuum region of the MS, where detection takes place. Several setups now exist for optimized quantitation and/or identification. Ion trap instruments are generally better suited for identification than are triple quadrupole instruments (higher MS power). Triple quadrupole instruments provide better information for quantification (faster scanning, higher sensitivity). Hybrid instruments exist that provide a linear ion trap in a triple ‘quad’ instrument in an attempt to make the best of both setups.

Several methods for simultaneous determination of mycotoxins have been reported, offering a significant

advantage over conventional techniques. For example, 13 *Penicillium* toxins (ochratoxin A, citrinin, patulin, mycophenolic acid, cyclopiazonic acid, PR-toxin, rubratoxin B, verruculogen, chaetoglobosin B, penitrem A, griseofulvin, roquefortin C, penicillic acid) have been determined in standardized matrix samples, including bread, rice, potatoes, vegetables, fruit, and other food. The LC-MS system used an ion trap instrument with electrospray ionization (ESI) and an atmospheric pressure chemical ionization (APCI) method. An LC-MS/MS method for ochratoxin A (OTA), zearalenone and two of its metabolites, DON and nivalenol, used a triple quad instrument with an ESI source from a pork liver matrix. The limits of quantification were as low as 1 µg per kg.

The use of a variety of ionization methods (fast atom bombardment (FAB) and APCI among them, for trichothecenes has been reported. FAB results in numerous different ions, whereas APCI, which has emerged as the method of choice for the major mycotoxins, provides a suitable spectrum for identification and quantification. Thermospray ionization (TSP) is being used less and less. Derivatization is not necessary, unless needed for additional fragments. The detection limits are in the lower nanogram per gram range. LC-TSP MS has also been used as a multi-mycotoxin method for the determination of several *Fusarium* mycotoxins together with zearalenone and OTA in the 1–40 ng per g range (see [www.mycotoxins.org](http://www.mycotoxins.org)).

### Preparation of Standard Solutions of Mycotoxins

Pure solutions of mycotoxins should be checked for concentration using spectrophotometry. Keep in mind that (1) pure solutions of mycotoxins (especially aflatoxins) should be handled with caution due to their carcinogenicity and (2) whereas stock solutions of mycotoxins ( $\sim 1 \text{ mg ml}^{-1}$ ) are rather stable for up to 1 year in the freezer, diluted solutions are unstable and most degrade with exposure to light. The following example is suitable for preparing stock solutions for aflatoxin B1.

Weigh  $\sim 1 \text{ mg}$  of aflatoxin and dissolve it in 100 ml of acetonitrile. Some suppliers provide mycotoxins as preweighed dry films in a vial; in that case, dissolve the film in the required volume of acetonitrile to get a solution of  $10 \text{ µg ml}^{-1}$ . With a calibrated spectrophotometer, measure the absorbance,  $A$ , at the wavelength of maximal absorption, which depends on the solvent used (355 nm in acetonitrile). Calculate the concentration of the stock solution by using the formula

$$\begin{aligned} &\text{Micrograms of aflatoxin B1 per milliliter} \\ &= A \times \text{molecular weight} \times 100/\epsilon \end{aligned}$$

where the molecular weight of aflatoxin B1 is 312 and the molar absorptivity,  $\epsilon$ , is  $2060 \text{ m}^2 \text{ mol}^{-1}$ .

The coefficient  $\epsilon$  also depends on the solvent used to dissolve mycotoxins (for instance,  $\epsilon = 2180 \text{ m}^2 \text{ mol}^{-1}$  in methanol). It is best to store the stock solution in the freezer as aliquots of 50 or 100 µl and to defreeze one aliquot to prepare working diluted solutions.

### Immunochemical Methods

Among the immunochemical methods, radioimmunoassay (RIA) and ELISA have been used for the determination of mycotoxins in foods and feeds. RIA tests have been developed for the determination of aflatoxins, T-2 toxin, ochratoxin, and zearalenone; however, taking into account the disadvantages of using radioactive substances such as the limited shelf-lives of reagents, the legislative restrictions for exchange or marketing of isotopes, and stringent specifications for facilities, RIA tests have become less and less popular, especially for routine analysis. In contrast, ELISA tests have been widely developed, marketed, and used for routine assays: they are rapid methods, and sometimes when very simplified (by using sticks for instance), they can be used as field methods requiring no laboratory apparatus, so that they could be used in industry or an industrial laboratory.

ELISA tests have been developed as direct and indirect techniques:

The direct technique, where the specific antibody against the mycotoxin is coated on the bottom of the 96 wells of a microtitration plate. The sample solution (extract) and a constant, known level of the toxin-enzyme conjugate are incubated simultaneously. After washing, the toxin-enzyme conjugate, which links to the wells through the antibody, is detected by adding a substrate specific to the enzyme. The resulting color is measured through photometry or visually detected by modification of the color of the medium in the wells.

The indirect technique, where the mycotoxin is fixed onto the 96 wells of the microplate through a toxin-polypeptide conjugate intermediary. The sample solution and a known constant concentration of the antibody are incubated simultaneously. After washing, the quantity of antibody bound to the plate is determined by adding an enzymatic conjugate 'enzyme-immunoglobulin' (specific antibody). The resulting color after adding the specific chromogenic substrate is measured using photometry or judged visually.

A variant of this type of ELISA can also be used: a 'specific antibody–enzyme' complex can also be synthesized and used for competition during the incubation. Thus, the use of a second antibody is no longer necessary, and the specific enzyme substrate can be added. In all these types, a standard curve is plotted using increasing quantities of standard mycotoxins.

The principle of the direct technique is often used in the development of screening tests: the mycotoxin content is performed by visual evaluation with a yes/no response at a specific cutting level. A lack of color indicates contamination of the sample by a mycotoxin above a specific cutting level. Such kits have been developed for instance on Nylon<sup>TM</sup> membrane under specific formats like

Cards such as 'EZ-screen<sup>TM</sup>' from R-Biopharm, which have been developed for total aflatoxins (cutting levels 20 and 5 µg per kg), for ochratoxin A, and for zearalenone (cutting levels of 20 and 100 µg per kg, respectively).

Cups such as 'Afla-20 Cup<sup>TM</sup>', from International Diagnostic System, working for total aflatoxins with cutting levels of 20 µg per kg.

Other formats for other mycotoxins at different cutting levels have also been developed by various research and development companies.

Determination test kits are based on direct but more often on indirect-type ELISA techniques. They use 96-well microtitration plates or beads or sticks. Analysis for mycotoxins can be completed within 3–4 h. This kind of test needs a photometric reader for the quantitation by plotting sample value against standard-curve derived values. Nowadays, a number of companies are developing such tests for aflatoxins, OTA, patulin, zearalenone, T-2 toxin, fumonisins, DON, etc. with limits of quantification as low as 1 µg per kg or even less.

The main advantages of the ELISA techniques are mainly the rapidity of analysis, the high sensitivity of detection (ultrasensitive tests), and the cost per unit sample, but the main drawback is the production of false positives (results being positive when no mycotoxins are present in the extract) and sometimes false negatives (results being negative when mycotoxins occur in the extract). Especially for food or feed complex matrices, such a limitation is very important and explains why ELISA procedures are seldom selected as official methods.

### Standard Procedures

The AOAC prescribes ~50 methods of analysis for mycotoxins. Here is a selection of TLC and LC methods.

AOAC 973.38, sterigmatocystin in barley and wheat – TLC method

AOAC 975.36, aflatoxins in foods and feeds – Romer minicolumn method

AOAC 975.38, ochratoxin A in green coffee – TLC method

AOAC 976.22, zearalenone in corn – TLC method

AOAC 980.21, aflatoxin M1 in milk and cheese – TLC method

AOAC 982.24 aflatoxins B1 and M1 in liver – TLC method

AOAC 985.18, zearalenol and zearalenone in maize – LC method

AOAC 986.17, DON in wheat – TLC method

AOAC 995.15, fumonisins B1, B2, and B3 in corn – LC method

AOAC 999.07, aflatoxin B1 and total aflatoxins in peanut butter, pistachio paste, fig paste, and paprika powder – immunoaffinity–LC method with postcolumn derivatization

AOAC 2000.02, determination of patulin in clear and cloudy apple juices and apple puree using HPLC

AOAC 2000.03, determination of ochratoxin in barley using HPLC and immunoaffinity cleanup

AOAC 2000.08, aflatoxin M1 in liquid milk using immunoaffinity column cleanup and HPLC

AOAC 2000.09, determination of ochratoxin in a roasted coffee using HPLC

AOAC 2000.16, aflatoxin B1 in baby food using an immunoaffinity column and HPLC

AOAC 2001.01, determination of ochratoxin A in wine using immunoaffinity column cleanup and HPLC

AOAC 2001.04, determination of fumonisins B1 and B2 in corn and cornflakes using HPLC and immunoaffinity cleanup

AOAC 2003.02, determination of aflatoxins in animal feed using immunoaffinity column cleanup and HPLC with postcolumn derivatization

## Safety Procedures

Mycotoxins should be handled as toxic substances, and special care should be taken when handling pure toxins in a dry form or samples (including TLC plates) that may be a source of dust. Accidental spillages of material containing toxin can generally be treated with 1% sodium hypochlorite bleach, left for 10 min, swabbed down with 5% aqueous acetone initially and subsequently with plenty of water.

Glassware exposed to aflatoxins can be rinsed with methanol and soaked in 1% sodium hypochlorite solution to which, after 2 h, acetone is added to 5%

of the total volume. The acetone is left for 30 min to destroy any potentially harmful but reactive intermediates formed by the hypochlorite and then washed thoroughly. It is known, for example, that aflatoxin B1 can form a carcinogenic derivative if treated with hypochlorite alone.

A very detailed discussion of laboratory decontamination and destruction of aflatoxins in laboratory wastes has been prepared for the International Agency for Research on Cancer.

## Neurotoxins

**M-T Fernández-Sánchez, A Ferrero, A Pérez-Gómez, and A Novelli**, University of Oviedo, Oviedo, Spain

## Introduction

The term neurotoxin applies to a variety of substances that can affect the nervous system producing a broad variety of effects usually harmful to human health, although in some cases these substances can be of therapeutic use. Neurotoxic compounds are occasionally present in food and beverages, and consumption of contaminated products may therefore contribute to the etiology of certain psychiatric disorders or neurodegenerative diseases in humans. Three different main groups of

food-related neurotoxins may be considered: (1) metal and organometallic compounds (e.g., mercury and methylmercury, lead, cadmium, manganese, aluminum, and alkyltin); (2) marine and freshwater toxins of algal origin; and (3) toxicants purposefully added or resulting from industrial activities and accumulated in food including organophosphates and polychlorinated biphenyls (PCBs). In addition to food-related toxic compounds, poisons from venomous species may also contain potent neurotoxins. The analysis of metals and organometallic compounds as well as of organophosphates and PCBs are covered by other articles within the Encyclopedia. The following is a discussion of a variety of methods for the analysis and detection of different types of marine and freshwater neurotoxins of algal origin, and for some neurotoxic compounds from snake, scorpion, and spider venoms.

### Definition of Vitamins and Their Function

Vitamins have been defined as a group of organic substances that, in minute amounts, are essential for normal metabolism of an organism. Like other essential nutrients vitamins have to be supplied by the diet in amounts covering the individual requirements of the organism in question which by definition is unable to synthesize these compounds. For a number of cases, e.g., disease and medication impair micro-nutrient status, pregnancy, people under stress, a supplementation with synthetic vitamins might be necessary to avoid vitamin deficiency and can help to prevent degenerative disorders. The natural source of the essential compounds that have vitamin activity for humans is the metabolism of microorganisms and plants. During evolution the ability to biosynthesize these substances was lost by the higher organisms, including humans. Sporadic vitamins, however, can be synthesized by humans – because all steps of the

biosynthetic pathway have been conserved – but only to an inadequate extent, e.g., niacin from the amino acid tryptophan or vitamin D<sub>3</sub> from its precursor cholecalciferol.

Vitamins are a chemically and functionally inhomogeneous group of biomolecules. As a gross classification distinction is usually made between (1) fat-soluble and (2) water-soluble vitamins. Owing to their insolubility in water the fat-soluble vitamins A, D, E, and K can be accumulated in fat tissue and excessive intake causes hypervitaminoses. The water-soluble vitamins – vitamin B<sub>1</sub>, vitamin B<sub>2</sub>, niacin, vitamin B<sub>6</sub>, folic acid, pantothenic acid, biotin, vitamin B<sub>12</sub>, and ascorbic acid – can generally only be stored in a small amount and intake exceeding actual need is excreted in the urine.

The terms used above for the substances that are actually considered as vitamins are trivial names, mostly group names, used for more than one derivative of a compound with similar biological activity. The function of vitamins in cell metabolism is just as varied as their chemical constitution. By virtue of their lipid solubility, fat-soluble vitamins generally affect physicochemical properties in various cell membranes. Furthermore, they act at the gene level as inductors of protein biosynthesis and as redox agents. The water-soluble vitamins act in many ways as coenzymes and thus enable the catalytic function of hundreds of enzymes.

A brief review of each of the vitamins describes their chemical composition, coenzyme forms, and main functions.

## Vitamin A

**Nomenclature.** Vitamin A: all retinoids with retinol-like biological activity. Retinoids, all native and synthetic forms of vitamin A, number ~1500 compounds.

**Chemical structure** (Figure 1). Molecules formally composed of four isoprene units; they naturally occur as an alcohol (retinol), an aldehyde (retinal), or as an acid (retinoic acid). From each of the three basic forms two variants exist: vitamin A<sub>1</sub> with a  $\beta$ -ionone ring and vitamin A<sub>2</sub> with a dehydrated  $\beta$ -ionone ring. Native retinoids show *cis-trans* isomerism of the double bonds. Carotenoids are proforms of vitamin A (Figure 2).

**General metabolic significance.** (1) Somatic functions: growth, development, and differentiation of epithelial and bone tissue (retinol, retinal, retinoic acid). (2) Reproduction: spermatogenesis, development of the placenta, embryonic growth (retinol, retinal). (3) Visual process: 11-*cis*-retinaldehyde is a prosthetic group of the visual pigments.

**Symptoms of deficiency.** (1) Night blindness. (2) Conjunctival and corneal xerosis. (3) Keratomalacia: ulceration and scarring of cornea that leads to loss of vision.

**Typical serum level.** About  $1.1\text{--}2.3\ \mu\text{mol l}^{-1}$ .

**Figure 1** Retinol and natural analogs. (A) All-*trans* retinol, (B) all-*trans* retinaldehyde, (C) all-*trans* retinoic acid, (D) retinylphosphate. Dotted lines in (A) separate the four isoprenoid units composing the molecule.

**Figure 2**  $\beta$ -Carotene.

## Vitamin D

**Nomenclature.** Vitamin D: all steroids with cholecalciferol-like biological activity; cholecalciferol (vitamin D<sub>3</sub>); 25-hydroxycholecalciferol (calcidiol); 1 $\alpha$ ,25-dihydroxycholecalciferol (calcitriol).

**Chemical structure** (Figure 3). 7-Dehydrocholesterol (provitamin D<sub>3</sub>) converted to cholecalciferol by UV irradiation; enzymatic hydroxylation to 25-OH-cholecalciferol in liver; enzymatic hydroxylation to 1 $\alpha$ ,25(OH)<sub>2</sub> colecalciferol in kidney.

**General metabolic significance.** Vitamin D stimulates intestinal absorption of calcium and phosphate, renal reabsorption of these ions, deposition and mobilization of minerals in the hard tissue, controlling normal calcium and phosphate blood level by means of these processes. Molecular mechanism of the vitamin D effects most frequently conform to the effect of steroid hormones (induction of protein biosynthesis).

**Symptoms of deficiency.** (1) Rickets in infants; (2) osteomalacia in adults.

**Typical serum level.** About  $75\text{--}175\ \text{pmol l}^{-1}$ .

## Vitamin E

**Nomenclature.** Vitamin E: group name for derivatives of 6-chromanol.

**Chemical structure** (Figure 4). Compounds composed of a chromanol-ring system, with two to four

**Figure 3** Cholecalciferol.

**Figure 4**  $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherol.

**Figure 5** Vitamin K: (A) vitamin K<sub>3</sub>, menadione; (B) vitamin K<sub>1</sub>, phyloquinone.

methyl groups in position 2 and a C<sub>16</sub> side chain, saturated in tocopherols and unsaturated in tocotrienols (four variants each).

**General metabolic significance.** Component of and interaction with biological membranes, protection of lipids against peroxidation, preservation of the membrane structure and integrity (exact molecular mechanism of vitamin E action unknown).

**Symptoms of deficiency.** In humans generally not due to dietary insufficiency but due to fat malabsorption syndromes or genetic abnormalities. Symptoms are difficult to categorize, e.g., reproduction disorders, abnormalities of muscles, liver, bone marrow, brain functions. At cellular level: increased oxidation of cell membranes.

**Typical serum level.** About 12–50  $\mu\text{mol l}^{-1}$ .

## Vitamin K

**Nomenclature.** Vitamin K (menadione, vitamin K<sub>3</sub>): group name for menadione and all of its derivatives with antihemorrhagic activity in vitamin K-deficient animals.

**Chemical structure (Figure 5).** Derivatives of naphthoquinone; natural forms contain an unsaturated isoprenoid side chain on C-3; parent compound 2-methyl-1,4-naphthoquinone (menadione, not thought to occur naturally); green plants contain 2-methyl-3-phytyl-1,4-naphthoquinone (phyloquinone, vitamin K<sub>1</sub>) with one double bond in the side chain.

**General metabolic significance.** Cofactor of a specific microsomal carboxylase, catalyzing  $\gamma$ -carboxylation of specific peptide bound glutamate residues.  $\gamma$ -Carboxyglutamate containing proteins: four of the clotting factors, plasma proteins C, M, S, and Z, osteocalcin, ovocalcin, atherocalcin.  $\gamma$ -Carboxyglutamate containing proteins mediate interaction with Ca<sup>2+</sup> and have specific functions in blood clotting and bone metabolism.

**Figure 6** Thiamine.

**Symptoms of deficiency.** In humans rare and mostly resulting from fat malabsorption syndromes, liver disease, and antibiotic therapy that inhibits microbial vitamin K<sub>2</sub> synthesis in the gut.

**Typical serum level.** About 2–17  $\text{nmol l}^{-1}$ .

## Thiamine

**Nomenclature.** Thiamine, vitamin B<sub>1</sub> (aneurin).

**Chemical structure (Figure 6).** Pyrimidine and thiazole moiety linked by methylene bridge – phosphorylated forms: thiamine monophosphate (TMP), thiamine diphosphate (TDP), thiamine triphosphate (TTP).

**Coenzyme form(s).** TDP.

**Enzymes with TDP as coenzyme in human metabolism.** (1) 2-oxoacid dehydrogenase (pyruvate dehydrogenase (EC 1.2.4.1)); 2-oxoglutarate dehydrogenase (EC 1.2.4.2); branched chain-2-oxoacid dehydrogenase(s) (EC 1.2.4.4); (2) transketolase (EC 2.2.1.1).

**General metabolic significance.** TDP-dependent enzymes in key positions of cell metabolism (carbohydrate catabolism, citrate cycle). Thiamine triphosphate, neurophysiologically active form of thiamine without coenzyme function (biochemical role not completely elucidated).

**Symptoms of deficiency.** Fatigue, irritability, lack of concentration due to marginal deficiencies: e.g., during pregnancy, lactation, heavy physical work, regular heavy alcohol intake. Beriberi includes dry beriberi (muscle wasting with heart involvement, tachycardia, etc.) and wet beriberi (edema, anorexia, muscle weakness, ataxia, peripheral paralysis) results from prolonged low dietary intake. Wernicke syndrome is characterized by mental disorder and frequently seen in alcoholics after long periods of alcohol intake without food intake.

**Typical serum level.** Less than 75  $\text{nmol l}^{-1}$ .

## Riboflavin

**Nomenclature.** Riboflavin, vitamin B<sub>2</sub> (lactoflavin, ovoflavin).

**Chemical structure (Figure 7).** 7,8-Dimethyl-10-(1'-D-ribityl)isoalloxazin – different redox states: flavochinon (Fl<sub>ox</sub>), flavosemichinon (Fl-H), flavohydrochinon (Fl<sub>red</sub>H<sub>2</sub>).

**Figure 7** Riboflavin.

*Coenzyme form(s).* FMN (flavin mononucleotide, riboflavin monophosphate), FAD (flavin adenine dinucleotide, riboflavin adenosine diphosphate).

*Enzymes with flavin coenzymes in human metabolism* (examples of ~100 enzymes). Electron-transfer flavo-protein (EC 1.3.99.2-3) FAD; NADPH-cytochrome-P-450-reductase (EC 1.6.2.4) FMN and FAD; succinate dehydrogenase (EC 1.3.99.1) FAD; D-amino acid oxidase (EC 1.4.3.3) FAD; L-amino acid oxidase (EC 1.4.3.2) FMN.

*General metabolic significance.* Flavin coenzyme dependent enzymes catalyze one-electron-transfer reactions, dehydrogenase reactions, reduction of  $O_2$  to  $H_2O_2$ , hydroxylations, etc. – numerous flavin enzymes dealing with biological oxidation.

*Symptoms of deficiency.* Oral, ocular, cutaneous, and genital lesions. Primary deficiency is associated with inadequate consumption of milk and other animal products. Secondary deficiencies are most common in chronic diarrheas, liver disease, chronic alcoholism, and postoperative situations.

*Typical serum level.* 110–640 nmol l<sup>-1</sup>.

## Niacin

*Nomenclature.* Niacin (vitamin PP): group name for nicotinic acid, nicotinamide, NAD, and NADP.

*Chemical structure* (Figure 8). Nicotinic acid (pyridine-3-carboxylic acid), nicotinamide (pyridine-3-carboxamide), NAD (nicotinamide adenine dinucleotide), NADP (nicotinamide adenine dinucleotide phosphate).

*Coenzyme form(s).* NAD, NADH, NADP, NADPH.

*Enzymes with niacin coenzymes in human metabolism* (examples of ~200 enzymes!). L-Lactate dehydrogenase (EC 1.1.1.27); alcohol dehydrogenase (EC 1.1.1.1); glyceraldehyde-phosphate dehydrogenase (EC 1.2.1.12); NADPH-cytochrome-P-450-reductase (EC 1.6.2.4).

**Figure 8** Niacin: (A) nicotinic acid, (B) nicotinamide, (C) nicotinamide adenine dinucleotide diphosphate.

*General metabolic significance.* Coenzymes participate in most hydrogen transfer reactions in every cell, thus in synthesis and catabolism of carbohydrates, fatty acids, amino acids, etc., as well as in production of metabolic energy. Biosynthesis is possible to a small degree from tryptophan.

*Symptoms of deficiency.* Marginal: multiple symptoms such as insomnia, loss of appetite, weight and strength loss, soreness of the tongue and mouth, burning sensations nervousness, etc. Pellagra: dermatosis, dementia, diarrhea. Risk groups: alcoholics and people from areas where corn is the major diet.

*Typical urine levels.* About 7–10 mg day<sup>-1</sup> (measured as N-methylnicotinamide).

## Pyridoxine

*Nomenclature.* Pyridoxine (vitamin B<sub>6</sub>): group name for pyridoxine (pyridoxol), pyridoxal, pyridoxamine and the 5'-phosphorylated derivatives of these compounds.

*Chemical structure* (Figure 9). Pyridoxine (3-hydroxy-2-methylpyridine) basal compound of the group; substitution (R) is carried out on 5'-C; pyridoxic acid is a catabolite of the compounds.

*Coenzyme(s).* PLP (pyridoxal phosphate), PMP (pyridoxamine phosphate).

*Enzymes with pyridoxine coenzymes in human metabolism* (examples, several hundred enzymes). (1) Transaminases (aspartate-aminotransferase (EC 2.6.1.1), alanine-aminotransferase (EC 2.6.1.2); aromatic-amino acid aminotransferase (EC 2.6.1.57)); (2) decarboxylases (histidine-decarboxylase (EC 4.1.1.22); aromatic-amino acid decarboxylase (EC 4.1.1.28)); (3)  $\alpha,\beta$ -elimination (L-serine-dehydratase (EC 4.2.1.13)).

**Figure 9** Vitamin B<sub>6</sub>: (A) pyridoxine, (B) pyridoxal, (C) pyridoxamine, (D) pyridoxic acid.

*General metabolic significance.* Pyridoxine dependent enzymes catalyze almost exclusively reactions of amino acid metabolism, also participating in heme synthesis and generation of biogenic amines.

*Symptoms of deficiency.* General: weakness, insomnia, nervous disorders, appetite and growth depression, dermatologic disorders. Vascular: arteriosclerosis, anemia, paralysis. Congenital: thrombosis, mental retardation, neuropathies.

*Typical serum level.* About 15–37 nmol l<sup>-1</sup>.

## Folic Acid

*Nomenclature.* Folic acid, pteroylglutamic acid (PteGlu) ‘folates’ also used as a group name for a family of more than 100 related compounds that have been modified on the pterin moiety, on N-5 and/or N-10, and on glutamyl side-chain.

*Chemical structure (Figure 10).* Pteroylglutamic (PteGlu) is composed of a pterin moiety, 4-aminobenzoic acid and glutamic acid and is the parent substance numerous ‘folates’.

*Coenzyme form(s).* Tetrahydrofolic acid (H<sub>4</sub>PteGlu); 5-methyltetrahydrofolic acid (5-CH<sub>3</sub>-H<sub>4</sub>PteGlu); 5,10-methylenetetrahydrofolic acid (5,10-CH<sub>2</sub>-H<sub>4</sub>PteGlu); 5,10-methenyltetrahydrofolic acid (5,10-CH<sup>+</sup>=H<sub>4</sub>PteGlu); formyltetrahydrofolic acid (5-HCO-H<sub>4</sub>PteGlu); 10-formyltetrahydrofolic acid (10-HCO-H<sub>4</sub>PteGlu); 5-formiminoj tetrahydrofolic acid (5-HCNH-H<sub>4</sub>PteGlu).

*Enzymes with folate coenzymes in human metabolism* (examples, ~20 enzymes). Thymidylate-synthase (EC 2.1.1.45); serine-hydroxymethyl-transferase (EC 2.1.2.1); formiminoglutamate-formiminotransferase (EC 2.1.2.5).

*General metabolic significance.* H<sub>4</sub>PteGlu (main coenzyme) transfers one-carbon units (with or without modification) from an appropriate donor to an

**Figure 10** Folic acid.

**Figure 11** D-(+)-Pantothenic acid.

appropriate acceptor. One-carbon units activated by H<sub>4</sub>PteGlu participate in the biosynthesis of purines, thymidylic acid, and certain amino acids and in activation of tRNA.

*Symptoms of deficiency.* Marginal: tiredness, irritability, loss of appetite. Severe: megaloblastic anemia, abdominal pain, diarrhea, ulcers, skin problems, hair loss, neurological disorders, depression. Deficiency during pregnancy may lead to premature birth or birth defect.

*Typical plasma/serum levels.* About 9–13.5 nmol l<sup>-1</sup>.

## Pantothenic Acid

*Nomenclature.* The term pantothenic acid is used for the ‘free’ acid, i.e., pantothenic acid itself as well as for the physiologically active forms coenzyme A and acyl-carrier protein.

*Chemical structure (Figure 11).* Pantothenic acid is composed of β-alanine and 2,4-dihydroxy-3,3-dimethylbutyric acid (pantoic acid), linked acid-amide-like.

*Coenzyme form(s).* (1) Coenzyme A, composed of cysteamine, pantothenic acid, phosphate, and adenosine-3',5'-diphosphate; (2) acyl-carrier protein.

*Biochemical function in human metabolism.* Activation of metabolites by coenzyme A while a thioester as a high-energy compound is generated. Examples: acetyl CoA, succinyl-CoA, acyl-CoA-derivates. The acyl-carrier protein is a component of the fatty acid-synthetase complex. Both coenzymes transfer acyl groups.

*General metabolic significance.* Acetyl CoA is a central compound of cell metabolism linking catabolic processes with generation of biological energy. Acetyl CoA is also a starting metabolite for biosynthesis of fatty acids, sterols, ketone bodies, etc.

*Symptoms of deficiency.* Headache, fatigue, insomnia, intestinal disturbance, paresthesia. (Only in severely malnourished patients!)

**Figure 12** Biotin.

*Typical urine levels.* About 7–10 mg day<sup>-1</sup> (measured as pantothenic acid).

### Biotin

*Nomenclature.* Biotin (vitamin H).

*Chemical structure* (Figure 12). Biotin (hexahydro-2-oxo-1H-thieno[3,4-d]imidazole-4-pentanoic acid). Biologically active analogs: biocytin ( $\epsilon$ -N-biotinyl-L-lysine), oxybiotin (S substituted by O).

*Enzymes with biotin as coenzyme in human metabolism.* Pyruvate carboxylase (EC 6.4.1.1); acetyl CoA carboxylase (EC 6.4.1.2); propionyl CoA carboxylase (EC 6.4.1.3); 3-methylcrotonyl CoA carboxylase (EC 6.4.1.4).

*General metabolic significance.* Biotin coenzymes participate in gluconeogenesis, biosynthesis of fatty acids, and metabolism of amino acids.

*Symptoms of deficiency.* Anorexia, nausea, vomiting glossitis, pallor, mental depression, alopecia, dry scaly dermatitis, increase in serum cholesterol and bile pigments. Very rare, e.g., after prolonged consumption of raw eggs.

*Typical serum/plasma level.* About 100–400 pmol l<sup>-1</sup>.

### Vitamin B<sub>12</sub>

*Nomenclature.* Vitamin B<sub>12</sub> (also used as a group name), cyanocobalamine (antipernicious anemia factor).

*Chemical structure* (Figure 13). Cyanocobalamine is composed of a corrin nucleus with a cobalt atom in its center. The cobalt atom is coordinately linked to a nitrogen of a 5,6-dimethylbenzimidazole group. Furthermore, the molecule contains ribose with an  $\alpha$ -glycosidic linkage. Substituents at the cobalt atom can be: CN group (cyanocobalamine), 5'-desoxyadenosyl (adenosylcobalamine), CH<sub>3</sub> (methylcobalamine) (numerous synthetic derivatives with different substitutes).

*Coenzyme form(s).* Adenosylcobalamine, methylcobalamine.

*Enzymes with vitamin B<sub>12</sub> as coenzyme in human metabolism.* (1) With adenosylcobalamine: methylmalonyl CoA-mutase (EC 5.4.99.2); leucine-2,3-aminomutase (EC 5.4.3.7); (2) with methylcobalamine: tetrahydropteroyltriglutamate methyltransferase (EC 2.1.1.13).

**Figure 13** Adenosylcobalamine.

**Figure 14** Vitamin C: (A) L-ascorbic acid, (B) dehydro-L-ascorbic acid.

*General metabolic significance.* Vitamin B<sub>12</sub> is essential to avoid certain forms of anemia and neurological disturbances.

*Symptoms of deficiency.* Pernicious anemia: glossitis, weakness, loss of appetite, loss of taste and smell, impotence, irritability, memory impairment, mild depressions, hallucinations. Cause of deficiency is usually not insufficient dietary intake but, e.g., inadequate digestion, lack of binding, and intrinsic factors.

*Typical serum/plasma level.* About 162–694 pmol l<sup>-1</sup>.

### Ascorbic Acid

*Nomenclature.* Ascorbic acid, vitamin C (hexuronic acid, antiscorbutic vitamin).

*Chemical structure* (Figure 14). L-Ascorbic acid (2,3-endi-ol-L-gulonic acid- $\gamma$ -lactone), dehydro-L-ascorbic acid (2-oxo-L-gulonic acid- $\gamma$ -lactone).

*General metabolic significance.* Ascorbic acid participates in numerous biological events concerning electron transport reactions, hydroxylations, oxidative catabolism of aromatic amino acids; one of the most important biologic redox systems (no coenzyme function).

*Symptoms of deficiency.* Scurvy: fatigue, bleeding gums, muscle pain, depression, dry skin, impaired iron absorption, impaired folate metabolism, impaired wound healing.

*Typical serum/plasma level.* About 20–100  $\mu\text{mol l}^{-1}$ .

## Physicochemical Properties of the Vitamins

Table 1 lists some physicochemical characteristics of the vitamins that might be relevant for the analysis of these compounds.

## Generalized Problems of Vitamin Analysis

The analysis of vitamins is a very wide and exciting field for analysts, due to a number of challenges that correspond to the nature of these analytes, e.g., their structural diversity with correspondingly different physical and chemical properties, the wide concentration ranges encountered, the relative instability of many vitamins (Table 1), and the occurrence of vitamers, metabolites, and various bound forms. Chemical diversity ranges from the relatively small and stable nicotinic acid (M 123) to the complex cobalamines, which belong to the largest known non-peptide, nonpolymer natural products (M ~1350). Typical concentration ranges encountered vary from picograms per milliliter, e.g., cobalamin in serum, to pure compounds analyzed in industrial quality control. All these facts pose high demands on methodology and analytical skills. It is thus not very surprising that a large array of techniques, ranging from traditional methods, like microbiology, to state-of-the-art technology, like high-performance liquid chromatography (HPLC) and tandem mass spectroscopy (MS/MS), have been used, and that even today vitamin analysis remains a challenge in many ways.

Methods employed largely vary from sample material to sample material, and for determination of most vitamins many different analytical methodologies can be used. Care must be taken in choosing the best method. Different methods can yield different results, e.g., due to different sample preparation or different specificity of the method toward the analyte. For example, the result of microbiological vitamin determinations is usually a 'biological activity' expressed as an amount of pure vitamin showing the same effect in the test. This assumption is often correct, but the possible presence and influence of, e.g., vitamers or metabolites with vitamin

activity also has to be taken into account. Thus, the same sample analyzed by HPLC–MS may yield a different vitamin content because with this technique chemically defined compounds are determined. The possible differences between results of different methods applied to the same sample should also be taken into account when literature data are examined. In the following, sampling, sample preparation, and different general methodologies for vitamin analysis are discussed.

## Sampling and Sample Preparation

During drawing a representative sample aliquot it has to be taken into account that many vitamins are sensitive to temperature, light, oxygen, or changes in pH, and should be analyzed as soon as possible after sampling. Especially natural samples such as vegetables and fruits are sensitive, and cannot be stored for long, even if kept deep-frozen, without losing significant amounts of their vitamin content. For example, the vitamin C content of vegetables can be used as an indicator of the conditions of their preparation or storage. Also important is the supply of a sample volume large enough for analysis, reflecting both the low vitamin contents in many samples, and a possible inhomogeneity of the material.

After sampling, the sample is prepared for analysis. Usually, each different type of sample material requires specially adapted sample preparation, extracting the vitamins from the matrix. This is often combined with a preliminary concentration and purification step. Roughly three application fields can be differentiated that pose different demands: determination of vitamin content in samples from human subjects and animals, e.g., plasma and tissue; determination of vitamin content in feed, food, plants, processed plants, plant products, and microorganisms; and determination of added vitamin content in fortified products, e.g., tablets, feed, or food.

Sample preparation should liberate the vitamin from the matrix, e.g., tissue or plasma, where it often occurs chemically or physically bound. Many specific transport binding proteins are known, e.g., for retinol. 'Chemical bonding' can include the incorporation of a vitamin into coenzymes, e.g., niacin and pantothenate in NAD and coenzyme A, respectively. Liberating vitamins from industrial product forms (formulations) is also an important issue. Here, vitamins are often encapsulated in small beadlets, e.g., from gelatin, which protects them from oxygen and makes them easier to add during processing.

To protect vitamins from decomposition, antioxidants such as BHT can be added during sample preparation. Saponification using alkaline alcoholic

**Table 1** Some important physicochemical properties of vitamins

Vitamin	Summation formula	Relative molecular mass	Factors influencing stability <sup>b</sup>								
			Absorption maximum <sup>a</sup> wavelength (nm)	Approximate solubility in H <sub>2</sub> O	O <sub>2</sub>	Reducing agents	Acid	Alkaline	Metal ions	100° C	Light/UV
Vitamin A	C <sub>20</sub> H <sub>30</sub> O (retinol)	286.4	325 (ethanol); 328 (isopropanol)	Insoluble	1	st	1	st	1	st	1
Carotenoids	C <sub>40</sub> H <sub>56</sub> (β-Carotene)	536.9	273; 452; 481 (petrol ether)	Insoluble	1	–	1	st	1	st	1
Vitamin D	C <sub>27</sub> H <sub>44</sub> O (vitamin D <sub>3</sub> )	384.6	264 (ethanol)	Insoluble	1	st	1	(st)	1	1	1
Vitamin E	C <sub>29</sub> H <sub>50</sub> O <sub>2</sub> (α-Tocopherol)	430.7	292 (ethanol)	Insoluble	1	st	st	(st)	1	st	(1)
Vitamin K	C <sub>31</sub> H <sub>46</sub> O <sub>2</sub> (vitamin K <sub>1</sub> )	450.7	243; 249; 260; 269; 325 (hexane)	Insoluble	(1)	(1)	st	1	1	st	1
Thiamine	C <sub>12</sub> H <sub>17</sub> ON <sub>4</sub> S × HCl (vitamin B <sub>1</sub> × HCl)	337.3	245 (0.1 mol l <sup>-1</sup> HCl)	1 g ml <sup>-1</sup>	(1)	(1)	st	1	1	(1)	1
Riboflavin	C <sub>17</sub> H <sub>20</sub> O <sub>6</sub> N <sub>4</sub>	376.4	233; 267; 374; 444	0.07 mg ml <sup>-1</sup>	(1)	(1)	st	1	1	st	1
Niacin	C <sub>6</sub> H <sub>5</sub> O <sub>2</sub> N (nicotinic acid)	123.1	261	0.2 g ml <sup>-1</sup>	st	(1)	st	st	st	st	st
Pyridoxine	C <sub>8</sub> H <sub>9</sub> O <sub>3</sub> N (pyridoxal)	167.2	291 (acidic); 254, 324 (neutral); 245, 309 (alkaline)	0–2 g ml <sup>-1</sup>	(1)	(1)	st	(1)	–	st	1

Ascorbic acid	C <sub>6</sub> H <sub>8</sub> O <sub>6</sub>	176.1	245 (pH 2); 265 (pH 6.4); 300 (pH 14)	0.9 g ml <sup>-1</sup>	1	st	st	1	1	(1)	(1)

<sup>a</sup>The solvent is in brackets (if essential).<sup>b</sup>1 = high lability; (1) = low lability; st = high stability; (st) = low stability.

From different sources (see Further Reading).

solution is used for vitamins such as retinol or tocopherol, which are stable under these conditions. A milder way is enzymatic sample treatment, e.g., with proteases and collagenases. This approach is especially used for plasma and tissue samples, and also for analysis of beadlets. A disadvantage can be a natural vitamin content of commercially available enzymes, which has to be determined and corrected accordingly. A special application is the determination of total pantothenate, including those present in coenzyme A. Liberation requires alkaline phosphatase, and a specific enzyme, pantetheinase, which has to be purified from pigeon liver prior to analysis. Denaturation of binding protein by addition of organic solvents is often used to free vitamins for plasma analysis, e.g., determination of retinol and tocopherol.

### Microbiological Methods

Historically, vitamins have been discovered as growth factors or compounds essential for life of humans, certain animals, and microorganisms. As these findings usually occurred before the exact chemical nature of the underlying active principle was known, experiments with animals or microorganisms were often the only way to test for the presence of vitamins. As soon as their structures were known and reference compounds became available, these tests could also be run in a (semi)-quantitative way. Set on a diet without the vitamin in question, the animal developed typical symptoms that could be cured by vitamin supplementation. These tests had some important disadvantages. It took relatively long before a result could be obtained, and, more important, the result often lacked specificity and accuracy as response varies from species to species. Applied to unknown samples often no chemically defined substance but rather biological activity could be determined.

Thus, of these methods mainly those using microorganisms are still in use, predominately for vitamins that are difficult to determine by classical instrumental analytical methods. This can be due to lack of suitable chromophores (biotin and pantothenate), very low concentrations (e.g., biotin and vitamin B<sub>12</sub>), or the presence of many active forms (folate) that are difficult to determine separately. The microbiological assay involves incubation of a sample extract with a suitable test organism for which the vitamin is essential for growth, often *Lactobacillus* spp. The growth of the bacteria in response to the vitamin can be monitored turbidimetrically and is quantified in relation to incubation with standard solutions. Main disadvantages are the long duration of the assay, usually 24 h, the chemical nonspecificity of the result (determination of

a biological activity), and its susceptibility to antibiotics and other inhibiting substances.

### HPLC

The method of choice for the determination of most vitamins is HPLC due to its high separation capability, its mild analytical conditions, and the possibility to use various specifically adapted detection methods, e.g., UV, fluorescence, or MS detection. All fat-soluble vitamins and most water-soluble vitamins have chromophores suitable for UV detection. Separation of vitamers and stereoisomers can be achieved. If a higher sensitivity is required HPLC with fluorescence detection can be used, either directly (e.g., vitamins A and E) or after derivatization (e.g., thiamine). A further improvement in sensitivity and specificity has been achieved by introducing HPLC with mass spectrometric detection in vitamin analysis. Due to the structural information retrievable, e.g., molecular mass, fragmentation pattern, this is the method of choice for analysis of samples with complex mixtures or low vitamin concentrations. Examples for the use of HPLC–MS in vitamin analysis include the determination of 25-hydroxy-D<sub>3</sub> and pantothenic acid. However, one drawback of mass spectrometry is the need for an isotopically labeled reference compound for reliable quantification. Due to the structural complexity of many vitamins, these reference compounds are often expensive and difficult to synthesize. An interesting unique application is the determination of vitamin B<sub>12</sub> by HPLC–IPC–MS, which is possible due to its cobalt content.

### Enzyme Assays

Enzyme assays are mainly used for determination of body status of vitamins. As vitamins usually function either as coenzymes or building blocks of coenzymes, the activity of the vitamin-dependent enzymes is a measure of vitamin status. Usually, the assay is carried out by determining the enzyme activity with and without activation by added coenzyme. The activity can be monitored by measuring changes in concentration of substrates or products during the reaction. An activation coefficient can be deduced, which reflects the status of the enzyme investigated, and thus the vitamin status. Most assays are conducted with whole blood or the separated erythrocyte fraction. They can be automated with clinical analyzers. Disadvantages include difficulties in assay standardization, instability of the enzymes during storage, and misleading results, e.g., due to conditions other than vitamin deficiency leading to low apoenzyme concentrations.

### Immuno- and Affinity Assays

Immuno- and affinity assays include a diverse range of methods, which have in common that at least one step is based on a selective binding of the vitamin to a binder, e.g., a transport protein. In immunoaffinity chromatography, this binding is used as a purification and/or concentration step. The vitamin, e.g., biotin, is loaded onto a column containing a selective binding protein, e.g., streptavidin. The vitamin is selectively retained on the column. After eluting other nonbinding sample ingredients the vitamin-protein complex is cleaved, and the now purified and concentrated vitamin is eluted.

In quantitative immunoassays, e.g., enzyme-linked immunosorbent assay and radioimmunoassay, a known amount of labeled vitamin is mixed with sample extract in which the vitamin content should be determined. Methods of labeling include radioisotopes (e.g., cobalamine), fluorescence, or luminescence markers (e.g., folate). The mixture is subjected to binding agent, equally forming complexes with both labeled and unlabeled vitamin. This complex is then isolated, and the amount of labeled vitamin present is measured. Sample vitamin concentration can be deduced from the ratio of labeled vitamin added to labeled vitamin measured after isolation. Advantages of immunoassays are short analysis time, and the possibility of automating them on clinical analyzers.

### Other Methods

Capillary electrophoresis can be used instead of HPLC for separation of complex samples, but has not yet found a broader application in vitamin analysis. Gas chromatography is rarely used as most vitamins are not volatile or stable enough for direct analysis. Applications include determination of vitamin D after derivatization.

### Automation of Vitamin Analysis

Automation of vitamin analysis is becoming more and more important, as it potentially offers significant time and resource savings. Automation is best applicable if large numbers of similar samples have to be analyzed. This is the case in clinical chemistry and in industry, for example, for quality control. In clinical chemistry many parameters including vitamins, e.g., ascorbic acid, folate, or cobalamine, can be determined using automated analyzers with a throughput of several hundreds of samples per day. These analyzers have only to be fed with the samples and reagents. Specialized software programs control the fully automated analyses, including calibration, dilutions, derivatizations, quantification, quality control, and interpretation of the results. Automation in

industry focuses on the use of bench-top robotic systems, e.g., for analysis of tablets, formulated vitamins, and product forms. Automated sampling and analyzing is used both for process and quality control.

## Interpretation of Analytical Data in Relation to Body Status

Chronically insufficient vitamin supply is undoubtedly a health risk. Severe vitamin deficiencies are characterized by symptoms that can be diagnosed quite clearly. They usually result from a highly insufficient intake of one or more vitamins over a long period of time and such deficiencies are still widespread in the developing countries. In the industrialized areas clinically distinct vitamin deficiencies are rare but marginal deficiency might be common in certain population groups, e.g., low income groups, teenagers, the elderly, alcoholics, pregnant and lactating women. To protect these groups from the consequences of insufficient vitamin supply, it is of great interest to have suitable methods to estimate the body status of vitamins. The skillful analytical techniques developed in the last decade are adequate for an exact quantification of vitamins in biological material. Less satisfying, however, is the evaluation of the analytical data concerning the true reflection of the 'body status' that mostly means tissue saturation with a certain vitamin. Threshold values concerning 'unsatisfactory supply' versus 'undoubtedly satisfactory supply' are difficult to define and the subject of controversial discussion.

In epidemiological examinations certain methods may also be used that yield statistically significant results at the population level. Nevertheless, the examination of an individual should lead to a clear evaluation of his or her particular nutritional situation.

To judge the value of the analytical data for estimation of the body status, knowledge of the intra-individual variation, i.e., day-to-day variation, is as important as information about the biological variation, i.e., reaction of the values to short and long time changes of intake and to other factors.

### Vitamin A

Concentration of vitamin A in blood serum is very stable and only drops when liver stores are exhausted. Thus, serum level does not reflect vitamin A status of the whole body. In the opinion of the World Health Organization neither intake data nor biochemical or clinical parameters are appropriate to estimate vitamin A status in humans. It recommends the use of more than one parameter to judge the risk of a marginal deficiency: intake records, level of plasma

retinol binding protein, and clinical symptoms. The value of determination of serum carotenoid concentration as an indicator is controversial.

### Vitamin D

The vitamin D plasma level does not adequately reflect its status in the whole body. Therefore, for the diagnosis of, for example, bone mineralization malfunctions, the determination of 25-OH-vitamin D<sub>3</sub> is preferred as a recognized clinical determinant.

### Vitamin E

A generally accepted procedure to estimate vitamin E status in humans does not seem to exist. However, in a number of studies a positive correlation between plasma cholesterol level and the levels of total lipids including cholesterol, triglycerides, etc., was observed. Thus, the plasma level of tocopherol should always be set in relation to the plasma lipids. A usual value of tocopherol is, e.g., 0.8 mg tocopherol per gram total lipids.

Other methods are also used for the determination of plasma/serum levels: *in vitro* lipid peroxidation in erythrocytes (malondialdehyde test); determination of vitamin E concentration in platelets; determination of tocopherols in fat tissue (needle biopsy).

### Vitamin K

Owing to different physical methods developed in the last few years a direct and specific determination of various derivatives of vitamin K in blood plasma is now practicable. These analytical data are considered as reflecting body status adequately. The conventional method of estimating the supply situation is, however, based on determining functions of vitamin-K-dependent plasma factors, especially of the prothrombin time. A more sensitive and more specific method to determine normal and abnormal prothrombin is radioimmunoassay.

### Thiamine

Standard methods for assessment of thiamine status used to be determination of erythrocyte transketolase ( $\alpha$ -ETK) activity (EC 2.2.1.1) with and without stimulation of this enzyme by addition of TDP cofactor (TDP TK effect). A TDP TK effect >15% is considered to show some degree of deficiency, whereas values >22% are considered to indicate severe deficiency. Technical difficulties, including standardization of the assay, instability of the enzyme during storage, and various conditions possibly influencing apoenzyme concentrations led to an increasing use of direct determination of TDP in whole blood, e.g., by HPLC in order to assess thiamine status. The HPLC assay is more robust and easier to perform. Thiamine

status determined by this method is considered to be in good correlation with results from TK activation assay. Usually, whole blood concentrations of 66.5–200 nmol l<sup>-1</sup> are encountered.

### Riboflavin

Riboflavin is the precursor for two important coenzymes, flavine adenine dinucleotide (FAD) and flavin mononucleotide (FMN), which represent the main 'body store' of riboflavin. Body status can be determined by direct and indirect methods. Direct methods include the determination of FAD and FMN in whole blood by HPLC. Usually, whole blood concentrations (FAD) of 175–475 nmol l<sup>-1</sup> are encountered. Another possibility for riboflavin status assessment is monitoring of urinary excretion. Values <27 µg per g creatinine point to deficiency, 27–79 µg per g creatinine are considered to be marginal, and values >80 µg per g creatinine to be normal. Urinary excretion sharply rises after tissue saturation is reached. Indirect methods include determination of erythrocyte glutathion reductase activity (EC 1.6.4.2), an FAD dependent enzyme. Results are often expressed as erythrocyte glutathion reductase activation coefficient (EGRAC), which reflects the ratio of apoenzyme to activated enzyme. Literature values indicating deficiency and normal status vary to some degree. EGRAC coefficients <1.20–1.4 are considered to be normal, whereas values >1.3–1.4 (–1.7) point to riboflavin deficiency.

### Niacin

The status of niacin in relation to most other vitamins is different as it can be synthesized by humans to some extent from tryptophan. Body status determination has been based on the determination of urinary excretion of niacin metabolites, predominately *N*-methyl-2-pyridone-5-carboxylamide and *N*-methyl-nicotinamide. The ratio of these compounds has been used as indicator of niacin status. Recent studies suggest that the determination of the two niacin-derived coenzymes, NAD and NADP, in erythrocytes, and their ratio are more reliable indicators of niacin status. However, a broadly accepted and easy to use determination method does not seem to exist.

### Pyridoxine

Pyridoxine status can be determined both by direct and indirect methods. Direct methods include determination of pyridoxal-5'-phosphate (PLP) in whole blood, and determination of urinary excretion of 4-pyridoxic acid (4-PA). The method of choice for quantification of both compounds is HPLC. Usually, whole blood concentrations of 35–110 nmol l<sup>-1</sup> PLP

are encountered. Concentrations of PLP have been found to be in good correlation with the pyridoxine status determined by indirect methods. Indirect methods measure the stimulated activation of pyridoxine-dependent enzymes in erythrocytes by addition of PLP. Mainly erythrocyte alanine aminotransferase activation coefficient (EALT-AC; EC 2.6.1.2) or erythrocyte aspartate aminotransferase activation coefficient (EAST-AC; EC 2.6.1.1) are determined. The coefficient activity with stimulation to activity without stimulation indicates the pyridoxine status. For EAST-AC, values  $>1.8$  are suggested to show deficiency,  $1.7$ – $1.8$  to be marginal, and  $<1.7$  to be adequate.

### Folic Acid

Folate status seems to be best reflected by whole blood concentration, as erythrocytes have significantly higher folate content than serum. Erythrocyte folate levels are also less susceptible to dietary fluctuations. However, methods for folate analysis in erythrocytes seem to be not yet as reliable as methods for serum analysis. Automated immunoassays that can be run on clinical analyzers have widely replaced the microbiological determination of folate. Serum concentrations  $<5.7 \text{ nmol l}^{-1}$  are suggested to point to deficiency,  $5.7$ – $11.4 \text{ nmol l}^{-1}$  to be marginal, and  $>11.4 \text{ nmol l}^{-1}$  to be adequate. Increased homocysteine levels can also point to folate deficiency.

### Biotin

Whereas severe dietary deficiency of biotin is very rare, except after consuming larger amounts of raw egg white, recent studies indicated that marginal deficiency might be more common than previously thought. Body status can be determined by measuring activity and/or activation of biotin-dependent enzymes, predominately carboxylases, e.g., erythrocyte pyruvate carboxylase (EC 6.4.1.1) by added biotin. More convenient methods are direct determination of biotin in plasma or serum by microbiological methods or avidin binding assays, or determination of excretion of biotin and 3-hydroxyisovaleric acid in urine. Serum concentrations from  $\sim 100$  to  $400 \text{ pmol l}^{-1}$  characterize a normal concentration range.

### Pantothenic Acid

As this vitamin is present in nearly all foods of plant and animal origin, dietary deficiency is practically unknown. Accordingly, little research has been conducted about assays to assess pantothenate status in man. Body status can be deduced from amounts of pantothenate excreted in urine, which equals  $4.5$ – $32 \text{ } \mu\text{mol day}^{-1}$ . A more convenient approach is

determination of pantothenate in serum, or preferably whole blood, by microbiological methods. Whole blood levels typically range from  $0.9$  to  $1.5 \text{ } \mu\text{mol l}^{-1}$ .

### Vitamin B<sub>12</sub>

Major vitamin B<sub>12</sub>-dependent metabolic processes include the formation of methionine from homocysteine, and the formation of succinyl coenzyme A from methylmalonyl coenzyme A. Thus, apart from directly determining vitamin B<sub>12</sub> concentration in serum, elevated levels of both methylmalonic acid and homocysteine may indicate a vitamin B<sub>12</sub> deficiency. Serum cobalamine concentration is often determined by automated immunoassays using an intrinsic factor as binding agent. These assays have mainly replaced the microbiological methods. Literature data about vitamin B<sub>12</sub> concentration in serum varies. Values  $<110$ – $150 \text{ pmol l}^{-1}$  are considered to reflect deficiency, whereas values  $>150$ – $200 \text{ pmol l}^{-1}$  represents an adequate status.

### Vitamin C

Vitamin C status can be assessed by measuring plasma levels or urinary excretion. However, due to practical disadvantages, e.g., quantitative sampling of urine and instability of vitamin C, determination of vitamin C in urine has been mainly replaced by determination of plasma levels. Methods include direct determination by HPLC, or automated assays based on a derivatization of ascorbic acid forming colored or fluorescent derivatives. While a plasma concentration  $<11.4 \text{ } \mu\text{mol l}^{-1}$  is widely used to characterize deficiency, literature data signifying adequate status vary from  $\sim >17$  to  $28.4 \text{ } \mu\text{mol l}^{-1}$ .

## Interpretation of Analytical Data in Relation to Bioavailability

The nutritional value of foods is not synonymous with their content of nutrients as determined by chemical analysis. Obviously, it is not enough to know how much of a nutrient, e.g., a vitamin, is present in the food, but we need to know how much of the biological potential inherent in the analyzed substance can be realized when the food is eaten. Thus, 'bioavailability' has to be considered, which has been defined as 'the portion of a nutrient capable of being absorbed and available for use or storage'.

Sensitive components of foods, like vitamins, are prone to many possible interactions in the food itself and/or in the body. Such interactions have a major influence on the final bioavailability, some being beneficial while others are harmful.

As a first level, problems related to nutrient availability might be located in storage, preparation, and

processing of foodstuffs. Bioavailability, in the widest sense of the term, is also implicated. A few examples may elucidate this.

Heat is the most commonly used agent in the preparation and processing of foodstuffs in order to achieve preservation, favorable texture and flavor changes, increased palatability, etc. Some vitamins are very sensitive to high temperatures (see **Table 1**) and can be entirely inactivated under different time/temperature conditions. But heating may also have advantageous effects by releasing some vitamins from binding proteins, for example, and thus converting them into absorbable form, or by destroying compounds like thiaminase, ascorbic acid oxidase, or avidin, which decompose or inactivate vitamins by binding.

Losses of vitamins also occur as a result of various operations like washing, peeling, crushing, etc., in household preparations as well as in industrial production, oxygen mostly being the deleterious agent. Interaction of some vitamins with heavy metal ions, especially copper, may also cause essential destruction.

These few examples may illustrate that data obtained by analysis of food raw materials have to be weighed critically with regard to their significance concerning real supply with a certain vitamin.

The next process that has to be taken into account is intestinal digestion and absorption. Some interactions with food and nonfood components can be presumed on this level, too. Dietary fiber and some minerals are candidates for such interactions, the significance of which has to be closely examined.

It has been repeatedly shown that intestinal transport of folic acid and of its derivatives has a pH-optimum of ~6. Folic acid bioavailability is reduced in certain clinical situations where human jejunal pH deviates from this value, such as sodium hydrogencarbonate dosing, prolonged administration of

alkaline drugs, some anti-epileptics, achlorhydria in the elderly, acute pancreatitis, etc. Even when intestinal absorption of a vitamin is normal, further problems of bioavailability might arise when the vitamin is transported in the bloodstream in a bound form. For example, retinol deficiency occurs despite a plentiful supply of retinol when protein deficiency limits the production of retinol-binding protein.

Research on bioavailability of vitamins is a modern field of biochemistry with a strong need for non-biological and biological analytical techniques to promote the understanding of the complicated subject of bioavailability.

## Introduction

The importance of the fat-soluble vitamins (A, D, E, and K) in both clinical chemistry and nutrition is well

recognized. Fat-soluble vitamin assays in foods are carried out for a variety of reasons including compliance to specifications, possible degradation by processing of the food, and food composition tables. Also, in clinical chemistry the fat-soluble vitamin levels provide useful information with regard to infective-morbidity, skin defects, and night blindness (vitamin A), rickets, osteomalacia and osteoporosis (vitamin D), radical mediated peroxidative processes (vitamin E), and blood coagulation plus other calcium-dependent processes (vitamin K). The four vitamins mentioned above all have an isoprenoid-related

processing of foodstuffs. Bioavailability, in the widest sense of the term, is also implicated. A few examples may elucidate this.

Heat is the most commonly used agent in the preparation and processing of foodstuffs in order to achieve preservation, favorable texture and flavor changes, increased palatability, etc. Some vitamins are very sensitive to high temperatures (see **Table 1**) and can be entirely inactivated under different time/temperature conditions. But heating may also have advantageous effects by releasing some vitamins from binding proteins, for example, and thus converting them into absorbable form, or by destroying compounds like thiaminase, ascorbic acid oxidase, or avidin, which decompose or inactivate vitamins by binding.

Losses of vitamins also occur as a result of various operations like washing, peeling, crushing, etc., in household preparations as well as in industrial production, oxygen mostly being the deleterious agent. Interaction of some vitamins with heavy metal ions, especially copper, may also cause essential destruction.

These few examples may illustrate that data obtained by analysis of food raw materials have to be weighed critically with regard to their significance concerning real supply with a certain vitamin.

The next process that has to be taken into account is intestinal digestion and absorption. Some interactions with food and nonfood components can be presumed on this level, too. Dietary fiber and some minerals are candidates for such interactions, the significance of which has to be closely examined.

It has been repeatedly shown that intestinal transport of folic acid and of its derivatives has a pH-optimum of ~6. Folic acid bioavailability is reduced in certain clinical situations where human jejunal pH deviates from this value, such as sodium hydrogencarbonate dosing, prolonged administration of

alkaline drugs, some anti-epileptics, achlorhydria in the elderly, acute pancreatitis, etc. Even when intestinal absorption of a vitamin is normal, further problems of bioavailability might arise when the vitamin is transported in the bloodstream in a bound form. For example, retinol deficiency occurs despite a plentiful supply of retinol when protein deficiency limits the production of retinol-binding protein.

Research on bioavailability of vitamins is a modern field of biochemistry with a strong need for non-biological and biological analytical techniques to promote the understanding of the complicated subject of bioavailability.

## Introduction

The importance of the fat-soluble vitamins (A, D, E, and K) in both clinical chemistry and nutrition is well

recognized. Fat-soluble vitamin assays in foods are carried out for a variety of reasons including compliance to specifications, possible degradation by processing of the food, and food composition tables. Also, in clinical chemistry the fat-soluble vitamin levels provide useful information with regard to infective-morbidity, skin defects, and night blindness (vitamin A), rickets, osteomalacia and osteoporosis (vitamin D), radical mediated peroxidative processes (vitamin E), and blood coagulation plus other calcium-dependent processes (vitamin K). The four vitamins mentioned above all have an isoprenoid-related

**Figure 1** Chemical structure of (A) vitamin A, all-trans-retinol; (B)  $\beta$ -carotene; (C) vitamin D, cholecalciferol; (D) vitamin E,  $\alpha$ -tocopherol; and (E) vitamin K<sub>1(20)</sub>, phyloquinone.

structure (Figure 1) and are liposoluble. This permits similar approaches for extraction. Other similarities include their sensitivity toward isomerization and oxidation by contact with daylight and their degradation by high temperatures. These properties result in a rather limited application of thin-layer chromatography (TLC) and gas chromatography (GC) to the analysis of fat-soluble vitamins in different matrices. On the other hand, in liquid chromatography (LC), the contact with air, light, and high temperatures can be minimized without loss of resolving power, speed, and sensitivity. Consequently, the number of LC applications to the analysis of the fat-soluble vitamins now largely supersedes other techniques (e.g., TLC and GC). A number of reviews dealing with these issues have recently become available.

## Vitamin A

### General Properties

The various forms of vitamin A (retinol, retinyl esters) are present in food of animal origin (liver, milk, meat) while its precursors (certain carotenoids) are present mainly in plant foods.

The retinyl esters from the food are hydrolyzed in the intestine and the resulting retinol is re-esterified in the mucosal cells, mainly with palmitic acid and associated with lymph chylomicrons. After being taken up by the liver parenchymal cells, retinyl esters are hydrolyzed again. Part of the liberated retinol is then transported in the plasma to peripheral tissues by the retinol binding protein–prealbumin complex. Another part is stored mainly as retinyl palmitate in the liver fat storing cells. Vitamin A is metabolized by oxidation of the cyclohexene ring, or by reversible oxidation to retinal and irreversibly to retinoic acid. Glucuronidation and oxidative cleavage of the side chain are further steps in the metabolic process.

Vitamin A is susceptible to oxidation and isomerization and, consequently, all manipulations such as sample collection, extraction, and storage should be carried out at low temperature and in subdued light.

Within cells, vitamin A (retinol, retinal, retinoic acid) functions mainly in vision, cellular differentiation, and embryogenesis. The adverse effects of vitamin A deficiency on complex physiological processes such as reproduction and the immune response result primarily from defective cellular differentiation.

### Methods of Extraction and Cleanup

When total vitamin A is to be measured regardless of whether it is free or esterified, a saponification step can be included. However, degradation of the retinoids occurs even under mild conditions and in the presence of antioxidants. Consequently, direct extraction procedures without any digestion step, allowing the separation and separate quantification of the ester forms and of retinol itself, have gained interest in the last two decades.

After a protein denaturation step with methanol, ethanol, or acetonitrile (in the case of blood samples) or after homogenization or lyophilization (in the case of food samples), extractions are usually performed with *n*-hexane, dichloromethane, or cyclohexane. Supercritical fluid extraction (SFE) has recently opened new perspectives because extraction conditions are milder and can be carried out at lower temperature. In addition, during the extraction the sample is in an inert atmosphere and protected from light, thus reducing further degradation of the vitamin A.

For samples with a high lipid content (e.g., milk), additional cleanup of the extracts may be necessary to eliminate other lipids such as triacylglycerols. In the past, open-column chromatography on magnesia, alumina, or silica gel has been used. More recently, solid-phase extraction (SPE) on disposable prepacked cartridges filled with silica or C<sub>18</sub> reversed-phase packing material has been applied to vitamin A analysis. SPE is a refinement of the earlier open-column chromatographic systems.

### Chemical Methods

Initial bioassay techniques were too time consuming to be employed on a routine basis and were superseded by physicochemical methods based on colorimetry, e.g., after reaction with antimony trichloride (Carr–Price reaction), or trifluoroacetic acid, or based on ultraviolet (UV) spectrophotometry or fluorimetry. However, these procedures cannot readily discriminate molecular species with different vitamin A activities (e.g., *cis-trans* isomers, retinyl esters, or oxidative degradation products).

### Chromatographic Methods

**Thin-layer chromatography** TLC is now rarely used for the analysis of vitamin A. High-performance thin-layer chromatography (HPTLC) together with densitometric scanning has been explored as a possible alternative, but is not widely used.

**Gas chromatography** The instability of conjugated unsaturated compounds such as retinol and retinyl esters, together with their degradation on incompletely inactivated column packing materials, has drastically hindered attempts of retinoid analysis by GC. However, when chromatographed on bonded phase capillary columns only a very low degree of decomposition is observed for retinol. Similarly, short chain retinyl esters have also been successfully chromatographed. By lowering the extent of decomposition of retinol on these capillary GC columns new perspectives are opened also toward gas chromatographic–mass spectrometric (GC–MS) determination of this compound, a technique that has recently been developed for studies of stable isotope-labeled vitamin A and carotenoids and the conversion of certain carotenoids to vitamin A in biological systems.

**Liquid chromatography** If research is focused on the separation of the different isomers of vitamin A, LC adsorption chromatography is the method of choice. Silica packing materials, and to a lesser

extent alumina, are then eluted with a nonpolar eluent based on *n*-hexane and a small percentage of a more polar solvent.

Normal bonded phase packing materials have been used as an alternative to adsorption chromatography because column deactivation due to contamination of polar contaminants injected is less frequently seen in the normal bonded phase than in adsorption chromatographic systems.

Reversed-phase packing materials (C<sub>18</sub> and C<sub>8</sub>) are utilized especially for the separation of the different retinyl esters and for combined vitamin A and carotenoid mixtures such as those in food extracts and clinical samples. Most semiaqueous mobile phases, consisting of mixtures of methanol or acetonitrile and water, result in chromatographic runs of more than 1 h to elute retinyl stearate. Gradient elution shortens this elution time but results in a loss of separation of two predominant esters, retinyl palmitate and retinyl stearate. More recently, isocratic non-aqueous reversed-phase (NARP) conditions with an acetonitrile–dichloromethane mixture resulted in a successful separation of the different esters within 15 min. The big advantage of NARP conditions over semiaqueous systems is the increased solubility of lipids. To compensate for this increased affinity of the compounds of low polarity for the eluent, highly retentive stationary phases are recommended.

A notable application of a polymeric C<sub>18</sub> phase (Vydac 201 TP) in the vitamin analysis was the separation of mono- and di-*cis*-retinols using a water–methanol–*n*-butanol mixture as eluent.

UV absorbance detection has been most widely used for vitamin A analysis. However, because retinol and retinyl esters are highly fluorescent, detection limits of one order of magnitude better than in assays with UV detection can be obtained using fluorescence detection. Also, electrochemical detection is a valuable alternative to UV and fluorescence detection provided the eluent contains water to incorporate essential electrolytes. Another detector for LC is the mass spectrometer. The LC–MS approach has also been applied to the analysis of vitamin A and its metabolites.

**Competitive protein-binding and immunological methods** As far as we know, no competitive protein-binding procedures or immunological methods are in common use for the determination of retinol.

### Examples and Limitations of Current Methodology

The limitations of techniques such as TLC and GC in vitamin A analysis have already been highlighted and

**Table 1** Representative procedures for the determination of vitamin A

Analyte(s)	Matrix	Sample preparation/extraction	Column	Mobile phase (v/v)	Detection

that LC is the technique for analysis in that area. Some representative procedures are brought together in Table 1.

## Carotenoids

### General Properties

Carotenoids are yellow to orange-red polyene pigments that strongly absorb ( $\epsilon > 100\,000\text{ mol l}^{-1}\text{ cm}^{-1}$ ) light in the 400–500 nm region of the spectrum. Of the  $\sim 600$  known representatives of this class, roughly 50, including  $\beta$ -carotene,  $\alpha$ -carotene, and  $\beta$ -cryptoxanthin possess vitamin A activity (Figure 1), i.e., can be intestinally cleaved to yield retinal. These compounds are sensitive to light, air, heat, and acid, which catalyze chain cleavage and/or stereoisomerization. The latter process involves a reversible conversion of the all-*trans* to the less stable *cis*-configuration and results in characteristic changes in the absorption spectrum and a decrease in vitamin A activity.

### Methods of Extraction and Cleanup

Carotenoids are commonly extracted from liquid samples (plasma/serum) into lipophilic solvents such as hexane, hexane–ethyl acetate, or diethyl ether, mostly after deproteinization with ethanol or methanol, which also helps to liberate the lipidic substances from protein binding. Extracts should be protected from light and acids and antioxidants may usefully be added. The extract is either used as such or is concentrated under oxygen-free nitrogen. Solid samples, e.g., foods, are either extracted with a solvent miscible with water (acetone, methanol) or, after dehydration of the sample, with a water immiscible solvent. Cleanup of the extract and fractionation of the pigments may involve saponification and/or open-column chromatography.

### Chemical Methods

Without prior fractionation the total concentration of carotenoids ('total carotenes') in a sample extract may be estimated by spectrophotometry at 450 nm (using an average molar absorptivity for calculation). As an improvement, in earlier times, individual carotenoids or carotenoid classes were collected after separation on alumina or magnesia-hyflo supercel columns and the absorbance of the eluted fractions measured. This approach once formed the basis of the Association of Official Analytical Chemists (AOAC) method for foods.

## Chromatographic Methods

**Thin-layer chromatography** The major value of TLC in the carotenoid area lay in prefractionation and identification rather than quantification. Detection was on the basis of color and can be achieved by densitometric scanning at 450 nm. Commonly used sorbents included silica gel and particularly magnesia, which exhibits high selectivity toward geometrical isomers of carotenoids. Octadecyl bonded silica (RP-18) had the advantage of being chemically less aggressive than the polar sorbents.

**Gas chromatography** Only perhydrogenated carotenoids have been found to be sufficiently volatile and thermostable to be amenable to GC. This approach is only valuable in connection with MS for identification purposes.

**Liquid chromatography** Normal-phase systems have the advantage of being directly compatible with extracts in hexane. Silica, alumina, and lime (calcium hydroxide) are all particularly suited to the resolution of carotenoid geometrical isomers (*cis-trans*) and diastereoisomers, but not positional isomers ( $\alpha/\beta$ -carotene). However, silica may cause on-column artifacts, reproducible retention on alumina is strongly dependent on a rigorous control of the water content of the eluent, and lime columns are not commercially available.

By far the majority of methods for the determination of carotenoids in biological materials nowadays are based on reversed phase chromatography. NARP eluents based on acetonitrile-methanol mixtures containing dichloromethane, chloroform, or tetrahydrofuran as a strong modifier are recommended for optimal sample solubility. The overall resolution reportedly benefits from the addition of hexane as a fourth component. Certain monomeric non-end-capped heavily loaded C<sub>18</sub> columns, e.g., Zorbax ODS, permit an isocratic separation of a wide range of carotenoids. Other systems use gradient elution to bridge the large polarity differences between xanthophylls (mainly hydroxyl- and epoxy-carotenes) and carotene hydrocarbons.

The resolution of geometrical isomers is readily accomplished on reversed-phase sorbents based on Vydac-type polymeric silica, unlike on monomeric phases on which all *cis* isomers usually co-elute. The exhaustive profiling of carotenoids in complex samples often requires the complementary use of a reverse phase (C<sub>18</sub>) plus a polar (cyano) sorbent. With modern equipment it is possible to achieve accurate and reproducible separation and quantitation of the major classes of carotenoids, retinoids, and

tocopherols by a 10 min LC run for extracts of plasma or other biological samples. However, the more demanding separation of very similar xanthophylls (e.g., lutein and zeaxanthin) and of lycopene derivatives may require gradient elution and hence longer run times of ~45 min.

SFC is emerging as an interesting tool for the separation of carotenoids, including positional and geometrical isomers, as well as for their identification, i.e., by coupling with MS.

Absorption detection at 450–470 nm is standard in the LC of carotenoids. Photodiode-array detection capable of recording the characteristic absorption spectra of carotenoid peaks forms the backbone of techniques for their identification in biological extracts, often complemented by LC-MS. Various analogs that have been used as internal standards for  $\beta$ -carotene have included apo- $\beta$ -carotenal, nonapreno- $\beta$ -carotene (C<sub>45</sub>), and  $\beta$ -apo-8'-carotenal-ethylxime.

## Competitive Protein Binding and Immunological Methods

Competitive protein binding and immunological methods for carotenoids are not generally available.

## Examples and Limitations of Current Methodology

The only technique that is of major interest for carotenoid analysis is LC. Selected applications to biological samples are presented in Table 2. These methods are mostly satisfactory in terms of selectivity and sensitivity. However, accurate quantification requires precautions because of relative lability of the analytes during sample preparation, their incomplete recovery from LC columns, and the limitations of the available internal standards.

## Vitamin D

### General Properties

The principal biological function of vitamin D is to act as precursor of 1,25-dihydroxyvitamin D, a circulating hormone that regulates calcium transport at several sites in the body, including calcium absorption in the gastrointestinal tract. This hormone, derived by two hydroxylations of the vitamin, firstly in the liver and then in the kidney, performs a wide range of regulatory functions that are implicated in human diseases. The best understood of these are the bone diseases that are classically associated with vitamin D deficiency, namely rickets and osteomalacia, which arise through failure of bone mineralization.

The term vitamin D covers the two natural compounds ergocalciferol (vitamin D<sub>2</sub>) and cholecalciferol

(vitamin D<sub>3</sub>) as well as a number of hydroxylated metabolites. Among the latter the 25-hydroxy- and 1,25-dihydroxyvitamin D are most prominent (**Figure 1**). The D<sub>2</sub> differs from the D<sub>3</sub> form by the presence of a double bond in its isoprenoid side chain. Both vitamins D<sub>2</sub> and D<sub>3</sub> are derived by photoirradiation from their respective diene sterol precursors (provitamin D). Of the 64 theoretically possible steric configurations the triene isomers tachysterol, isotachysterol, and 5,6-*trans*-caldiol are of analytical interest. The triene moiety confers a characteristic UV absorption ( $\lambda_{\text{max}} = 264 \text{ nm}$ ,  $\epsilon = 18\,300 \text{ mol l}^{-1} \text{ cm}^{-1}$ ) upon the molecule. Vitamin D is moderately sensitive to heat and air, which catalyze isomerization to previtamin D and oxidation, respectively.

### Methods for Extraction and Cleanup

Saponification using ethanolic KOH is sometimes useful to eliminate the bulk of neutral fat from lipid-rich samples such as milk, but should preferably be avoided for stability reasons. A sample preparation scheme for vitamin D analysis usually involves a double phase solvent extraction followed by a column chromatographic cleanup step. Depending on the polarity of the solvent system used, this lipid extraction can include either total (vitamin D + metabolites) or be selective (one target metabolite or a group of metabolites). Examples of solvents affording the extraction of ‘total vitamin D’ include chloroform–methanol (Bligh and Dyer) or dichloromethane–methanol. The parent vitamin D partitions into low polarity solvents, e.g., hexane or cyclohexane. Mixtures of these with ethyl acetate or an alcohol are employed for the isolation of metabolites and have the additional advantage of disrupting the vitamin D binding protein complex. Alternative extraction solvents are based on diethyl ether, dichloromethane, benzene/toluene. Column chromatography serves a double purpose, i.e., removal of interfering lipids and prefractionation into classes of vitamin D metabolites. Minicolumns or prepacked cartridges containing Sephadex LH-20, hydroxyalkoxypropylsephadex, alumina, silica, or bonded phases (amino, octadecylsilane) can be used.

### Chemical Methods

Direct UV–visible spectrophotometric determination of vitamin D is limited to pure dosage forms that should not even contain other fat-soluble vitamins. In an older colorimetric AOAC procedure the absorbance of a colored product resulting from the reaction of vitamin D with antimony trichloride was measured at 500 nm. However, the other fat-soluble vitamins, particularly vitamin A, as well as the

vitamin D triene isomers interfered and, hence, had to be removed. Alternative colorimetric procedures employed trifluoroacetic acid, trichloroacetic acid, or  $\alpha$ -dichlorohydrin as dehydrating agents.

### Chromatographic Methods

**Thin-layer chromatography** TLC, particularly in its HPTLC version, can be considered as a (less expensive) alternative to LC for the purification and prefractionation of lipid extracts prior to gas chromatographic or radioligand assays of vitamin D metabolites in biological materials. In foods, vitamin D has been determined by HPTLC-photodensitometry, either at 266 nm or, after spraying with chromogenic reagents, at higher wavelengths. As a technique to separate vitamin D analogs, including irradiation products of provitamin D and the different fat-soluble vitamins, TLC has been replaced by LC with SPE cleanup columns that have replaced TLC for the cleanup process.

**Gas chromatography** GC of vitamin D and its metabolites is subject to a number of unfavorable phenomena, including on-column adsorption, dehydration of 25-hydroxy derivatives, and thermal rearrangement involving B-ring closure, yielding pyro and isopyro isomers. The latter is prevented by derivatization to isotachysterols, using acyl chlorides, acyl anhydrides, or HCl in a chlorinated solvent. With biological samples, flame ionization and electron capture detection lack sufficient selectivity to avoid the interference of other lipids, e.g., cholesterol, so that extensive sample pretreatment is required. Detection of trimethylsilyl- or *t*-butyldimethylsilyl derivatives by electron impact or chemical ionization mass spectrometry results in superior selectivity and sensitivity, thus permitting the determination of vitamin D, 25-hydroxyvitamin D, and several dihydroxylated metabolites in plasma or foods. Deuterium-labeled analogs or dihydrotachysterol are candidate internal standards.

**Liquid chromatography** On silica or polar bonded phases (nitro, cyano), the separation of vitamin D metabolites occurs according to the number and position of hydroxyl groups in the molecule. Binary mobile phases are usually based on hexane–2-propanol mixtures. Improved resolution of normally co-eluting D<sub>2</sub> and D<sub>3</sub> hydroxylated metabolites is afforded by ternary solvent systems containing dichloromethane as a third component. However, the D<sub>2</sub> and D<sub>3</sub> parent compounds remain unresolved in any normal-phase system.

Reversed-phase LC with water–methanol or water–acetonitrile as mobile phases is suitable for the resolution of vitamin D<sub>2</sub> and D<sub>3</sub> and the 25-hydroxy-metabolites, but exhibits inferior selectivity for the dihydroxylated metabolites. When it is to be applied to biosamples a normal-phase LC prefractionation is mostly required for selectivity reasons.

Vitamin D and its metabolites can be detected on the basis of their native UV absorption ( $\lambda_{\text{max}} = 264 \text{ nm}$ ) or after conversion to isotachysterols ( $\lambda_{\text{max}} = 301 \text{ nm}$ ). However, because of the inherent poor selectivity and sensitivity of this approach quantitation is mostly performed offline by a radioligand assay. Several metabolites have also been determined in plasma by LC–thermospray MS.

Vitamin D<sub>2</sub> is a straightforward choice as an internal standard for vitamin D<sub>3</sub>, whereas 5,6-*trans*-caldiol has been used in an LC assay of 25-hydroxyvitamin D<sub>2</sub> and 25-hydroxyvitamin D<sub>3</sub>.

### Competitive Protein Binding and Immunological Methods

A large number of radioligand assays have been reported for the quantitative determination of vitamin D metabolites in biosamples. In radioreceptor assays the target protein is either the vitamin D binding protein from blood or a specific tissue receptor. Antibodies used in radioimmunoassays originate from sheep or rabbits. The traditional one- or two-dimensional LC cleanup prior to radioligand assays of vitamin D metabolites is increasingly replaced by a solid-phase purification on cartridges.

Assays for 25-hydroxyvitamin D (caldiol) and 1,25-dihydroxyvitamin D (calcitriol) in human and other animals' plasma samples are commonly performed nowadays by kit assays that are based on competitive protein-binding or immunoassays, either with or without a preliminary cleanup on SPE cartridges. Although there is some ongoing controversy about details of ultimate accuracy and of possible interferences, these kit assays have proved in practice to be clinically useful, highly sensitive, and are much simpler to use than the alternative LC approach. External quality assurance schemes such as 'DEQAS', operated from Charing Cross Hospital, are invaluable adjuncts to laboratory performance which greatly help to improve interlaboratory harmonization and to detect and resolve any methodological problems at an early stage.

### Examples and Limitations of Current Methodology

A number of representative methods for the determination of vitamin D and its metabolites in biological samples are presented in Table 3. The major

<sup>a</sup> Abbreviations used: see also **Tables 1** and **2**; SPE, solid-phase extraction; MS, mass spectrometry (*m/z* value); CPB, competitive protein finding; RIA, radioimmunoassay.

limitation of the LC procedures lies in the lack of highly sensitive detection options for these analytes, thus necessitating the use of radioligand assays for quantification. Although intrinsically selective and sensitive, the latter still require extensive sample purification to remove the bulk of lipids and to differentiate individual metabolites. The obvious alternative is GC-MS, but even with this sophisticated technique the determination of metabolites that occur in the subnanogram range (e.g., 1,25-dihydroxyvitamin D) remains an analytical challenge.

## Vitamin E

### General Properties

There is a considerable body of research that indicates that vitamin E has important antioxidant, or redox-modulatory, functions in cell membranes and other lipidic sites in the body, which include especially the prevention of pro-oxidant (including oxygen free radical) damage by peroxidation of the polyunsaturated lipids. Recent studies suggest that vitamin E also has cell-signaling functions. The different chemical forms of vitamin E have different metabolic fates, and may also have different functions from each other. However, the roles and significance of vitamin E in chronic human diseases have yet to be fully elucidated.

Vitamin E is a collective term for tocopherols and tocotrienols, a series of 6-chromanol derivatives substituted by a saturated (as in tocopherols) or a partially unsaturated (tocotrienols) isoprenoid side chain and one to three methyl groups (**Figure 1**). The principal form in the body is  $\alpha$ -tocopherol (5,7,8-trimethyltocol), which in nature occurs as the 2*R*,4'*R*,8'*R*-diastereomer. Totally synthetic  $\alpha$ -tocopherol (all-rac- $\alpha$ -tocopherol) is a racemate of all possible stereoisomers, whereas a semisynthetic racemic  $\alpha$ -tocopherol (2-ambo- $\alpha$ -tocopherol) is a mixture of the 2*R*,4'*R*,8'*R* and the 2*S*,4'*R*,8'*R* (2-epi) diastereoisomers. The natural dimethyltocols  $\beta$ - and  $\gamma$ -tocopherol are structural variants.  $\gamma$ -Tocopherol is a major component of certain foods. All vitamin E derivatives possess strong reducing properties. They are relatively stable to heat and alkali in anoxic conditions but their oxidation is promoted by alkali and metal ions in the presence of air. Tocopherols and tocotrienols absorb light in the UV region ( $\lambda_{\max} = 292\text{--}295\text{ nm}$ ,  $\epsilon = 3530\text{ mol l}^{-1}\text{ cm}^{-1}$ ) and are natively fluorescent ( $\lambda_{\text{exc}} = 205\text{ and }295\text{ nm}$ ,  $\lambda_{\text{em}} = 330\text{ nm}$ ) and can be electrochemically oxidized. The latter two properties are lost in  $\alpha$ -tocopheryl acetate where the phenolic hydroxyl group is blocked.

### Methods for Extraction and Cleanup

Standard lipid extraction methods may be used for the isolation of vitamin E from a biological matrix. The addition of oxidants (pyrogallol, ascorbic acid, butylated hydroxytoluene) is necessary when saponification is included as purification before extraction. This is useful in connection with the analysis of erythrocytes, tissues, foods, and vegetable oils, but generally does not require plasma. However, saponification may negatively affect the recovery of tocopherols and particularly tocol, a potential internal standard, from lipid-rich samples. Another pretreatment for plasma, erythrocytes, and tissues that reportedly results in cleaner extracts is with sodium dodecyl sulfate. Methods for solvent extraction of tocopherols fall into two categories, i.e., double phase extraction, using hexane, hexane-ethyl acetate, diethyl ether, butanol-ethyl acetate, or chloroform-methanol, and monophasic extractions with water-miscible solvents. Depending on the selectivity of the analytical technique, it may be necessary to remove lipid interferences, particularly cholesterol, from the extract. This can be done by digitonin precipitation, open-column chromatography on silica, florisil, or digitonin-impregnated celite, and by TLC.

### Chemical Methods

In pure samples such as pharmaceutical products tocopherols can sometimes be directly determined by UV spectrophotometry. Improved selectivity is derived from the Emmerie-Engel reaction, based on the reduction by tocopherols of iron(III) ions to iron(II) ions. The latter form a red complex with 2,2'-bipyridyl or bathophenanthroline, which can be measured colorimetrically ( $\lambda_{\max} = 520\text{ nm}$ ). However, as many reducing substances, including carotenoids and sterols, interfere with the reaction, their removal by column chromatography or TLC is imperative. Such prefractionation should also be carried out in the spectrofluorimetric assays of vitamin E, although these are more specific than the colorimetric ones.

### Chromatographic Methods

**Thin-layer chromatography** Historically TLC has had great merits in vitamin E assays as a cleanup step in connection with colorimetry or GC and, for a long time, as the only technique capable of separating  $\beta$ - and  $\gamma$ -tocopherols. This separation was accomplished either by using complex mobile phases in one-dimensional approach or, alternatively, in two-dimensional systems. For quantitative purposes photodensitometric scanning after HPTLC separation has been conducted both in the transmittance and the

reflectance modes, on native tocopherols, after their oxidation to tocopherylquinones or after spraying with chromogenic reagents. The latter sometimes differentiate on a color basis between particular tocopherols.

**Gas chromatography** GC on capillary columns, unlike on packed columns, is capable of separating  $\beta$ - and  $\gamma$ -tocopherols and suffers less from the interference of cholesterol in biological extracts. After prefractionation by LC, GC is capable of resolving all eight  $\alpha$ -tocopherol diastereomers. Although all tocopherols and tocotrienols have been separated in a single run, without derivatization on a WCOT column, a conversion of the phenolic hydroxyl group to TMS ethers, acetate, or butyrate esters is often advantageous for reasons of peak symmetry. The most powerful potential of GC for vitamin E analysis lies in its easy combination with MS. In the selected ion monitoring (SIM) mode using a deuterated internal standard GC-MS has permitted the sensitive quantification of  $\alpha$ -tocopherol in minute amounts of lung and ocular tissues. For the routine determination of vitamin E in biological materials GC with flame ionization detection has been largely superseded by LC.

**Liquid chromatography** The main analytical application of normal-phase chromatography is the resolution of positional isomers of tocopherols and tocotrienols. This is readily accomplished on silica and certain polar bonded phases (amino or aminocyno but not cyano) using hexane-diisopropyl ether or hexane-2-propanol mixtures as eluents.

An advantage of normal-phase systems is their compatibility with extracts in nonpolar solvents. Thus, normal-phase chromatography lends itself very well to the determination of individual tocopherols and tocotrienols in samples of vegetable oils, after a simple dissolution in hexane. As in most other relevant biological samples (plasma/serum, erythrocytes, platelets, feces, tissues, and foods) the content of  $\beta$ -tocopherol is negligible, routine methods for the quantification of the  $\alpha$ -,  $\gamma$ -, and  $\delta$ -homologs are based on reversed-phase chromatography. The isocratic separation of  $\alpha$ -,  $\gamma$ -, and  $\delta$ -tocopherols or tocotrienols is straightforward on any reversed-phase column, but the positional isomers always co-elute. Tocotrienols elute ahead of the corresponding tocopherols. Mobile phases usually consist of methanol with a small percentage of water or sometimes nonaqueous mixtures with strong modifiers. The addition of electrolytes, e.g., perchlorate or acetate, to semiaqueous eluents permits the electrochemical detection of vitamin E. Biological extracts in nonpolar solvents

have to be evaporated to dryness and reconstituted with the mobile phase prior to injection on a reversed-phase column. In contrast, alcoholic extracts resulting from a monophasic extraction can be directly injected without concentration, on condition that sufficient sensitivity and selectivity are provided by the detector (see below).

The highest sensitivity and selectivity in vitamin E LC assays are obtained by using fluorescence or electrochemical detection. In the former, excitation at the low wavelength (205 nm) leads to improved detection limits but at the expense of selectivity, compared with the use of 295 nm. Electrochemical detection in the oxidation mode (amperometry or coulometry) is another factor 20 times more sensitive. In routine practice, however, most vitamin E assays employ the less sensitive absorbance detection at 292–295 nm (variable wavelength instrument) or 280 nm (fixed wavelength detectors). If retinol and carotenoids are included, a programmable multi-channel detector, preferably a diode array instrument, is needed. As noted previously, combined LC assays for vitamins A, E, and carotenoids are now in common use for clinical chemistry and can measure about a dozen components within a  $\sim 10$  min run. The NIST and UK EQAS external quality assurance schemes permit interlaboratory comparisons of performance for these assays.

The choice of a suitable internal standard in quantitative work is practically limited to tocol,  $\alpha$ -tocopheryl acetate (only with absorbance detection), or  $\delta$ -tocopherol (if absent in the sample) in reversed-phase systems and tocol or 2,2,5,7,8-pentamethyl-6-chromanol in normal-phase chromatography.

### Competitive Protein Binding and Immunological Methods

No competitive protein binding or immunological methods have been reported for vitamin E.

### Examples and Limitations of Current Methodology

Table 4 lists a number of recent LC and GC-MS methods for the determination of vitamin E in bio-samples.

Because of the versatility in detection and the relatively high concentration of vitamin E in foods and physiological samples, the available LC methods show few shortcomings in terms of selectivity, sensitivity, and routine applicability. In those cases where extra sensitivity is required GC-MS can be considered. However, there is still room for improved methods to separate the diastereomers.

## Vitamin K

### General Properties

Biological samples may contain any or all of three forms of vitamin K: vitamin K<sub>1(20)</sub> (phyloquinone) which is synthesized by green plants and found in chloroplasts of photosynthetic plants and is the major form of vitamin K in plant and most animal foods; vitamin K<sub>2</sub>, a group of vitamers (menaquinones) synthesized by bacteria and ranging from MK-4 to MK-13 according to the number of isoprene units in the side chain, and finally synthetic vitamin K<sub>3</sub> (menadione), which exhibits vitamin K activity by virtue of its *in vivo* conversion to menaquinones, chiefly MK-4. The latter is a pharmaceutical and water-soluble form which does not occur in food and unlike the other forms is toxic at high intakes. Such water-soluble derivatives of menadione are used as animal feed supplement but owing to toxicity to humans menadione cannot be used in human medicine or as a food supplement.

Phylloquinone of either dietary or endogenous (bacterial) origin is rapidly concentrated in the liver where it is further metabolized, mainly to its epoxide. Apart from instances of fat-malabsorption and cases of hemorrhagic disease of early life, especially in some exclusively breast-fed babies, overt and unequivocal vitamin K deficiencies are rare. However, there is increasing evidence to suggest that vitamin K status may be very important for a variety of physiological processes and for health status, especially in older people, by virtue of its effects on certain components and processes of aging bone and of the vasculature. Research activity in these areas of biochemistry and epidemiology is currently intense.

Phylloquinone (vitamin K<sub>1(20)</sub>) and also the other K-vitamins are destroyed in alkaline medium and isomerize in daylight. They are easily reduced but are fairly stable toward oxidizing conditions and heat.

It has been demonstrated that vitamin K<sub>1(20)</sub> is an essential cofactor in the post-translational carboxylation of glutamic acid residues (GLU) to  $\gamma$ -carboxyglutamic acid residues (GLA) in a number of blood clotting factors (II, VII, IX, and X) and in some other proteins such as protein C, protein S, and osteocalcin, the latter being an important component of bone that can also be measured in the blood stream.

### Methods of Extraction and Cleanup

Before vitamin K<sub>1(20)</sub> can be extracted from blood samples, denaturation of its transport proteins (lipoproteins) is necessary. Ethanol, methanol, or 2-propanol is frequently used for this purpose. For

extraction of vitamin  $K_{1(20)}$  from milk samples lipase treatment is to be preferred over alkaline saponification due to the instability of the compound.

Following the hydrolysis and/or denaturation step, vitamin  $K_{1(20)}$  can be extracted either in a monophasic procedure with a mixture of methanol and dichloromethane, or by a biphasic extraction with *n*-hexane. The selectivity, however, of the above-mentioned extractions is rather low and a lot of interfering (lipophilic) compounds are co-extracted. More recently, SFE was also applied to the analysis of vitamin  $K_{1(20)}$  in infant formula. In these procedures the vitamin is adsorbed onto silica gel and eluted before further separation.

### Chemical Methods

In the early days of vitamin  $K_{1(20)}$  discovery, colorimetric and UV-visible spectrophotometric methods were applied for identification and quantitative purposes. Also, the formation of fluorescent derivatives has been described. Other physicochemical methods include titration with cerium(IV) sulfate, polarography, microcoulometry, and phosphorimetry. These methods, however, have now been largely replaced by modern chromatographic techniques such as LC and to a lesser extent GC and TLC.

### Chromatographic Methods

**Thin-layer chromatography** TLC procedures for vitamin  $K_{1(20)}$  can be divided into three main types: (1) adsorption chromatography on silica plates enabling the separation of *cis-trans* isomers, (2) argentation chromatography to separate saturated and unsaturated homologs of vitamin  $K_{1(20)}$ , and (3) reversed-phase chromatography enabling the separation of methylated and demethylated K-vitamer.

These systems are somehow complementary to each other. Despite the introduction of HPTLC and densitometric scanning, the explosive advances of LC in the past decades explain the rapid decline of TLC applications in the vitamin K area.

**Gas chromatography** The high retention times and the on-column degradation of the K-vitamer always hampered the application of GC techniques in this area. However, both vitamin  $K_{1(20)}$  and  $K_1$  epoxide can be chromatographed on OV-17 as well as on CP-Sil 5 columns. Detection is then performed in the flame ionization detection mode or preferably with electron capture detection. The latter procedure results in higher sensitivity and increased selectivity.

**Liquid chromatography** Adsorption chromatography facilitates the separation of *cis*- and *trans*-vitamin

$K_{1(20)}$ . Furthermore, it is the method of choice for a further cleanup of crude extracts of blood or food samples. Under well-defined conditions, vitamin  $K_{1(20)}$  is then separated from different classes of lipids but co-elutes with the internal standard, which is typically a homolog of vitamin  $K_{1(20)}$  that does not occur naturally in the sample. The fraction containing both vitamin  $K_{1(20)}$  and the internal standard is then collected, concentrated to dryness, and used in a further analytical chromatographic step. Modern detection systems can eliminate the evaporation step by increasing the detection sensitivity.

Similar to adsorption chromatography, also on normal bonded phase packing materials, *cis*- and *trans*-vitamin  $K_{1(20)}$  can be separated.

Reversed-phase chromatography is the method of choice for the final step of vitamin K assays. It can easily separate vitamin  $K_{1(20)}$  from lipids with closely related polarities and from structural analogs used as internal standard. Similar to the other fat-soluble vitamins nonaqueous reversed-phased systems are preferable because of the increased solubility of vitamin  $K_{1(20)}$  and co-extracted lipids in the eluents that can be used.

The most interesting aspect of K-vitamer analysis by LC, however, is the detection mode. UV detection, the traditional detection mode, is only suitable for quantification of high levels of vitamin  $K_{1(20)}$ , e.g., after administration of pharmacological doses. Vitamin  $K_{1(20)}$  also exhibits electrochemical activity. Electrochemical detection, however, requires a semi-aqueous mobile phase to support the conducting electrolyte. This restricts the applications to reversed-phase chromatography unless the electrolyte is added postcolumn. The latter procedure however, results in a drastic loss in sensitivity. Reductive electrochemical detection of K-vitamer suffers from oxygen interference and passivation of the working electrode. Dual electrode detection in the redox mode, on the other hand, improves both the sensitivity and the baseline stability.

A third and currently preferred option to detect K vitamer in LC is fluorescence detection. Vitamin  $K_{1(20)}$  does not show native fluorescence, and consequently a number of procedures have been developed to modify vitamin  $K_{1(20)}$  into a fluorescent molecule. A first procedure consists of the use of a coulometric detector as a postcolumn reactor to reduce vitamin  $K_{1(20)}$  to the fluorescent hydroquinone form. Reduction of vitamin  $K_{1(20)}$  can also be obtained by a chemical reaction, either by a reagent that is added postcolumn or one that is incorporated in the eluent itself. In both cases elevated temperature is necessary for the reaction (thermally induced wet-chemical reaction). Alternatively, and currently preferred, the

<sup>a</sup> Wavelength (nm), etc.<sup>b</sup> Abbreviations, see **Tables 1–4**; SFE, supercritical fluid extraction; MSD, mass selective detection.

reduction can also be performed at room temperature on a solid-phase reactor packed with zinc metal particles. Besides the hydroquinone forms, the photodecomposition products of vitamin K<sub>1(20)</sub> are fluorescent. This phenomenon resulted in a third procedure to detect K-vitamins after a high-performance liquid chromatographic separation, namely postcolumn photochemical reaction detection. With modern equipment it is possible to quantitate vitamin K in as little as 0.25 ml human plasma from nonsupplemented subjects, a considerable improvement in sensitivity over previous assays. An external quality assurance scheme (KEQAS) is run from St. Thomas' Hospital, London.

### Competitive Protein Binding and Immunological Methods

As far as we know there is no immunological method available for the determination of the K-vitamins.

### Examples and Limitations of Current Methodology

Some of the most relevant procedures for the analysis of K-vitamins are brought together in Table 5. It should be clear that again LC is the technique of choice, as this technique is applied both to the sample cleanup and to the analytical measurement of vitamin K<sub>1(20)</sub> in different matrices. As with all modern analytical programs, a keystone for success is a sound quality control and assessment strategy, which should always include the exchange of samples between different analytical laboratories and the use of round robin external quality assurance schemes wherever possible.

### Vitamins and Their Properties

Foods contain ~40 essential nutrients, which can be divided into four main groups: nutrients of energy metabolism, essential amino acids, macro and micro mineral elements, and vitamins. Vitamins are a group of organic substances, of which four are fat-soluble and nine are water-soluble. The latter group consists of vitamin C (ascorbic acid), and eight vitamins of

group B (B<sub>1</sub>, thiamin; B<sub>2</sub>, riboflavin; B<sub>3</sub>, niacin (nicotinic acid); B<sub>5</sub>, pantothenic acid; B<sub>6</sub>, pyridoxine; biotin; folate/folic acid; B<sub>12</sub>, cobalamins). The B-group vitamins are now more commonly referred to directly by name. Designations such as B<sub>3</sub>, B<sub>5</sub>, etc. are only found in the older literature. Each of these actually contain one or more vitamins, in addition to the parent compound. The classical definition of vitamins states that these essential nutrients are not formed in humans, and must be obtained through the diet. Rich food sources of certain water-soluble vitamins include yeast, liver, wheat germ, and vegetables. They are stored only to a limited extent in the body. Most are absorbed efficiently, and occur mainly in the water phase of the body. When this becomes saturated, any excess of the water-soluble vitamins is

excreted through the kidneys in urine. Water-soluble vitamins are relatively nontoxic when compared to fat-soluble vitamins, and thus relatively high doses are usually well tolerated.

Water-soluble vitamins participate in a vast number of enzymatic reactions, in most cases in the form of co-enzymes. Many of these enzymatic reactions are well characterized. Many biochemical pathways in the body necessitate several different and specific enzymatic reactions, each having its own vitamin-containing co-factors.

The number and chemical variety of vitamin co-enzyme forms, and the instability of many of their reduced forms, have made it difficult to separate and quantify vitamins in complex mixtures. In general, crystalline water-soluble vitamins are relatively stable in the presence of air, whereas in solution some are easily oxidized. They are generally most stable in acidic media, and least stable in alkaline ones (Table 1). Their degradation in solution is further dependent on the temperature, the presence or absence of oxygen, and the presence or absence of metal ions. Biological

**Table 1** Major chemical characteristics of the water-soluble vitamins and their co-enzyme forms

<i>Vitamin or respective active coenzyme form(s)</i>	<i>Major chemical characteristics</i>
AA, DHA	AA is a strongly reducing dibasic acid with a $pK_1$ of 4.1 and a $pK_2$ of 11.8. It is easily oxidized by several agents (e.g., oxygen, halogens, hydrogen peroxide), especially in aqueous solutions, to form DHA. This reaction is initially reversible, since DHA can be reduced to AA by agents such as glutathione, but subsequent ring-opening converts DHA to diketogulonate, which is an irreversible reaction in the body. Oxygen, heavy metal ions ( $Cu^{2+}$ , $Ag^+$ , $Fe^{3+}$ ), and alkaline pH especially favor the oxidation of AA to DHA. Oxidation of DHA is irreversible.
Thiamin, TPP	Thiamin in aqueous solution is most stable between pH 2 and 4, and labile at alkaline pH. It is also heat labile. TPP is stable in aqueous solution at pH 2–6 and at 0°C. In alkaline oxidation these form fluorescent thiochromes.
Riboflavin, FMN, FAD	Riboflavin is a yellow-green naturally fluorescent compound. Riboflavin and FMN are very easily destroyed by UV radiation. When protected from light, riboflavin is rather stable at neutral and slightly acidic pH. FAD is also more stable at acidic pH, and even at elevated temperatures.
Niacin, $NAD^+$ , $NADP^+$ , and reduced forms NADH and NADPH	Nicotinic acid is stable in acid and alkali, even when heated. Nicotinamide is very stable only in neutral solution. The oxidized co-enzymes (NAD, NADP) are most stable in acidic conditions; aqueous and neutral solutions are less stable. In alkaline pH the decay is accelerated. The reduced co-enzymes (NADH, NADPH) are rapidly destroyed in acid. In alkali they are more stable, although they tend to oxidize after long periods of time. Note that in the older literature the niacin co-enzymes that are now abbreviated to NAD, NADP, etc. were formerly known as (i.e., abbreviated to) DPN, TPN, etc.
Pantothenic acid, CoA, CoASH	Pantothenic acid is most stable in a slightly acidic medium (pH 4–5). Both in acid and alkali it is cleaved. The salt form of pantothenic acid is even more stable. CoA is relatively stable in solutions of pH 2–6.
Pyridoxine, PLP	Highly photosensitive. Otherwise relatively stable, although PLP is easily oxidized or hydrolyzed.
Biotin	Biotin is very stable; it is even autoclavable in concentrated sulfuric acid.
Folic acid (PGA), tetrahydrofolate, 10-formyltetrahydrofolate, and 5-methyltetrahydrofolate	Natural folates are easily oxidizable, whereas folic acid (PGA) is not. The use of antioxidants in sample preparation is mandatory. AA and reducing thiols are widely used. Alkaline pH and heating can result in the conversion of 10-formyltetrahydrofolate to other folates and degradation products.
Cyanocobalamin, AdoCbl, MeCbl	Cyanocobalamin is stable in aqueous solution between pH 4 and 7, and can be heated without significant loss. Cyanide can be split off on exposure to light. AdoCbl and MeCbl are extremely photosensitive. They are both stable in neutral aqueous solution in the dark, and withstand heating.

AA, ascorbic acid; AdoCbl, adenosylcobalamin; CoA, co-enzyme A; DHA, dehydroascorbic acid; TPP, thiamin pyrophosphate; FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; MeCbl, methylcobalamin;  $NAD^+$ , nicotinamide adenine dinucleotide;  $NADP^+$ , nicotinamide adenine dinucleotide phosphate; PLP, pyridoxal phosphate; PGA, pteroylglutamic acid.

samples may contain oxidation products of the vitamins. Therefore, it is essential that samples are suitably preserved immediately after collection. Acidification, protein precipitation, addition of reducing agents (e.g., thiols), and freezing are some of the necessary measures in vitamin analysis. Some vitamins (e.g., flavins) are light sensitive, and this must be taken into account in the analysis for these substances. Addition of chelating agents (to remove metal ion catalysts) and even removal of oxygen (by inert gas) may be necessary in the assays of oxidizable vitamins. However, some water-soluble vitamins, such as nicotinic acid and biotin, are stable even in conditions of extreme pH and heat.

## Methods of Extraction and Cleanup

Water-soluble vitamins have been determined using a wide range of analytical methods: biological (including microbiological), chemical, physicochemical, chromatographic, and immunological. The need for purification and the method of cleanup for analytical samples greatly depends on the vitamin and/or vitamins to be measured, the analytical method that is to be used, and on the sample material. The physicochemical properties of vitamins may place limitations on the methodology. Furthermore, the sample matrix must be taken into consideration. The vitamin/vitamin concentration in a sample may also vary greatly: pharmaceutical vitamin preparations typically have the highest concentrations, and in biological samples their concentration may be very low. In the latter case, concentration and efficient separation from other interfering substances is a paramount requirement for successful analysis.

Manipulation in the analysis of biological samples (plasma, urine, tissue samples) is designed to decrease the amount of protein and other interfering material, and it may be necessary also to control the oxidation/reduction state of the vitamin. The chemical characteristics of the vitamins (Table 1) are of

major importance when choosing the method. Reduction of the protein content may be accomplished by precipitation using acid, heating, or organic solvent. The release of some vitamins from the corresponding esters or conjugates (e.g., folate polyglutamates, thiamin phosphate esters) may demand enzymatic or acid hydrolysis.

The use of solid-phase extraction cartridges is now well established in the analysis of clinical specimens. However, although this method provides efficient purification of the sample, it may lead to a loss of protein-bound vitamins. Direct injection of plasma samples into liquid chromatography (LC) columns is possible in some applications. Dilute filtered or centrifuged urine can be injected in certain LC applications, as is the case in urinary riboflavin assay.

The analysis of foods follows a similar procedure. Liquids (e.g., milk, juice, and infant formula) often require the same process as is applied for plasma or urine, although here lipid removal may also be needed. Solid food is mechanically disrupted or homogenized and hydrolyzed when necessary, followed by extraction or dissolution in a suitable buffer or solvent plus hydrolytic enzyme treatment to release the vitamins from their bound forms, especially those in vitamin-containing enzymes. The analytical method may be directly applied to a clarified supernatant or may require further concentration and purification of the sample, e.g., on a solid-phase extraction cartridge prior to analysis. Table 2 shows an outline of the sample preparation scheme for the determination for thiamin and riboflavin in different foods. This sample preparation procedure efficiently reduces sample matrix interferences and excess oxidizing reagent is flushed off. The extraction cartridge concentrates the vitamins when very low levels are to be analyzed. The subsequent LC analysis is shown in Figure 1 for selected foods.

Pharmaceutical multivitamin preparations can often be analyzed after minimal manipulation: in chromatographic analysis, the finely powdered material is

**Table 2** Outline of the sample preparation for determination of thiamin and riboflavin in foods

---

Add 2.5 g of finely ground sample to 50 ml of 0.1 mol l <sup>-1</sup> HCl and sonicate for 5 min.
Autoclave at 121°C for 30 min.
Cool and adjust pH to 4.5 with 2 mol l <sup>-1</sup> sodium acetate.
Add 2.5 ml of 5% diastase and incubate at 45–50°C for 3 h.
Pipette 4.0 ml of a filtered or centrifuged sample extract into a test tube and add 3.0 ml 1% potassium hexacyanoferrate(III) in 15% NaOH solution and vortex for 10 s.
Allow 1 min for oxidation and add 3.0 ml of 3.75 mol l <sup>-1</sup> HCl and vortex for 10 s.
Condition a C <sub>18</sub> Sep-Pak with 5 ml of methanol followed by 5 ml of 5 mmol l <sup>-1</sup> ammonium acetate pH 5.
Load 5 ml of reacted sample onto C <sub>18</sub> Sep-Pak (dropwise), and rinse with 5 ml 5 mmol l <sup>-1</sup> ammonium acetate pH 5.
Elute thiochrome (oxidized thiamin) and riboflavin from the Sep-Pak with 4 ml of methanol/5 mmol l <sup>-1</sup> ammonium acetate, pH 5 (60/40), and inject into the liquid chromatograph.

---

dissolved, or liquid extract is diluted in the mobile phase containing the internal standard. After clarification of the supernatant, appropriate aliquots are injected directly into the LC column. Moreover, the number of vitamers, i.e., different chemical forms used in pharmaceuticals, is generally, rather, limited.

## Methods of Analysis

The earliest methods for vitamin analysis were based on animal bioassays. Later, when it was recognized that vitamins are essential for certain microorganisms, microbiological tests were evolved. The chemical methods for determination of water-soluble vitamins were quite common in the past, before the development of more specific and selective analytical methods.

### Chemical Methods

Chemical determination without separation can be exploited, especially in the analysis of pure or highly concentrated samples such as some foods (e.g., fruit juice and other liquid formula) and pharmaceuticals. Biological samples often contain unknown compounds that can cause nonspecific interference in less sophisticated assays. The chemical methods usually lack the specificity and sensitivity in the quantitative determination of vitamins in biological samples or differentiation between different vitamers.

The physicochemical properties of the water-soluble vitamins are extensively utilized in chemical methods. A method for quantitative vitamin C (ascorbic acid, AA) measurement in food and physiological samples is based on a reaction of the keto groups in dehydroascorbic acid (DHA) with *o*-phenylenediamine (OPD) to give a fluorescent quinoxaline. This method involves the oxidation of AA to DHA, followed by the measurement of 'total AA' in the sample. The reductive capabilities of AA can especially be utilized for direct electrochemical (amperometric or coulometric) measurement when coupled with HPLC separation.

By alkaline oxidation with cyanogen bromide or potassium hexacyanoferrate(III), thiamin can be converted into an inactive product, thiochrome, which is strongly fluorescent in ultraviolet (UV) radiation. The same reaction also occurs with thiamin phosphate esters without affecting the phosphate bond. The cyanogen bromide-based assay is susceptible to interference by some drugs. Riboflavin has a natural brilliant greenish-yellow fluorescence in UV radiation, thus providing a means of quantification pharmaceuticals, and some biological samples.

Alternatively, at alkaline pH riboflavin can be photochemically converted to lumiflavin, which can be specifically extracted with chloroform for subsequent analysis.

Direct fluorimetry of pyridoxal phosphate and pyridoxal is unreliable due to interfering fluorescent compounds, and thus sample cleanup prior to the assay is required. Oxidation of pyridoxal phosphate to pyridoxic acid phosphate by alkaline cyanide, or reaction with bisulfite or semicarbazide can enhance the fluorescence and hence the sensitivity of the assay.

The reactivity of biotin with several reagents can be exploited in some chemical assays like its reaction with diazo derivatives, or the reaction of the ureido ring with *p*-dimethylaminocinnamaldehyde in an acidic medium, but the sensitivity of these assays is relatively poor. Several methods described for biotin assay involve a competitive 'complex' formation between biotin and avidin bound with a chromophore/fluorophore probe. In these assays, biotin, which has a higher affinity for avidin, quantitatively displaces the probe from the complex.

A more specific type of chemical assay is based on enzymatic measurement of vitamin co-enzyme activity. This approach is designed to detect a vitamin deficiency in tissues, and is only feasible for those vitamins that serve as co-enzymes. For instance, thiamin depletion in a subject can be diagnosed by measuring the transketolase activity in red blood cells with and without the addition of thiamin pyrophosphate (TPP) *in vitro*. If TPP increases the activity by more than a given amount, thiamin deficiency is indicated. Similarly, a subnormal level of riboflavin is indicated in tissues if the activity of erythrocyte glutathione reductase is increased after the addition of flavin adenine dinucleotide (FAD). Erythrocyte transaminase activation by pyridoxal-5'-phosphate (PLP) can be measured to establish a deficiency of vitamin B<sub>6</sub>.

### Chromatographic Methods

Chromatographic vitamin assays are now widely used. These methods are often capable of separating and determining different vitamers, and even several vitamins and vitamers simultaneously. LC has proved to be the most powerful analytical technique for several vitamins. Detection can be by light absorption (visible or UV), fluorescence, electrochemical detection, or mass spectrometry (MS). Polarography has been used in some instances. Gas-liquid chromatography (GC), thin-layer chromatography (TLC), capillary electrophoresis, tandem mass spectrometry, and other chromatographic methods are less often used for routine analyses.

LC has proved to be one of the most useful techniques for the analysis of water-soluble vitamins and their vitamers in foods, body fluids, tissues, and pharmaceuticals. One example of LC analysis can be seen in **Figure 2**, which demonstrates the separation of eight different vitamins in a single analysis. The main advantage of LC is its versatility in column technology and detection methods. The basic LC instrumentation is nowadays becoming less expensive. Recent improvements such as column switching technique, robotics in sample preparation, and especially computerized chromatogram processing increase versatility and reduce the 'hands-on' time considerably. One apparent drawback of LC technology is the expertise needed in method development and, to some extent, in its use. Some typical LC conditions applicable to water-soluble vitamin analyses are shown in **Table 3**.

Ion-exchange and reversed-phase media are most commonly used as stationary phases in the LC analysis of water-soluble vitamins. Aminopropyl-bonded silica columns (e.g., LiChrosorb NH<sub>2</sub>,  $\mu$ Bondapak NH<sub>2</sub>) have been used as weak anion exchangers for

**Figure 2** Reversed-phase LC separation of eight water-soluble vitamins. Column: Vydac 201HS54. the simultaneous assay of many of the water-soluble vitamins (thiamin, riboflavin, pyridoxine, cyanocobalamin, AA, folic acid, niacin, niacinamide, and calcium pantothenate) in multivitamin preparations. Relatively few applications are available for more complex samples, e.g., for foods and biological samples using these columns, because better separation is achieved in reversed-phase media, which has the added flexibility of combination with a range of ion-pairing reagents; see below. Amino columns, however, are frequently used for the determination of AA in foods and biological samples. The mobile phase in assays based on amino columns consists of an acidic buffer (phosphate, acetate, or citrate, pH usually between 2.5 and 5) and an organic modifier (e.g., methanol or acetonitrile).

A monomolecular octadecyl layer bound to a porous microparticulate silica support is a basis for modern reversed-phase LC column technology. The popular abbreviations used for such columns include C18, RP, and ODS. Octyl (C8) and phenyl phases are other forms of the reversed-phase medium that have also been used for water-soluble vitamin analysis. The possible ionization of water-soluble vitamins must be taken into consideration (e.g., the carboxyl functions of glutamic acid in folate, the hydroxyl groups of ascorbic acid, etc.) when adjusting the pH of solution. It is usual to mask these ionizable groups to enable interaction of the analyte with the nonpolar stationary phase. This may be accomplished either by using an acidic pH for the mobile phase to cause complete protonation or by using an ion-pairing agent in the mobile phase. Tetrabutylammonium

salts, and pentane-, hexane-, heptane- or octanesulfonic acid are frequently used for the latter purpose. Organic modifiers that are often used in the mobile phase of phosphate or acetate buffers include methanol and acetonitrile. A sufficient chromatographic separation in most cases is achieved by isocratic elution (Figure 1). Gradient elution may be indicated for certain complex samples or multivitamin analyses (Figure 2).

Three methods of detection (UV absorbance, fluorescence, and electrochemical activity) are applicable for the analysis of water-soluble vitamins. Currently, UV absorption detection is used in many LC applications for water-soluble vitamins. A simultaneous assay of several vitamins with several wavelengths along with information of peak purity can be accomplished with a diode array absorbance detector. The detection limit of a UV detector is in the order of 1–10 ng (10–100 pmol), which is poorer than that of fluorescence and electrochemical detectors but often sufficient for analysis for many vitamins in foods and physiological samples (Table 4). The lack of selectivity of UV detection may cause problems with interfering and co-eluting contaminants especially in biological samples, thus necessitating sample purification prior to LC.

Several vitamins are naturally fluorescent, a physical characteristic that can be used in their sensitive and selective detection in LC. The detection limit for riboflavin by fluorescence detection is less than 1 pmol, whereas in UV detection it is ~30 times higher. The detection of an LC assay for thiamin and its phosphate esters using the fluorimetric

**Table 4** Water-soluble vitamin content of selected foods and physiological samples

<i>Vitamin or coenzyme<sup>a</sup></i>	<i>Source</i>	<i>Method<sup>a</sup></i>	<i>Result</i>
Ascorbic acid	Human plasma	LC, UV	20–80 $\mu\text{mol l}^{-1}$
	Human milk (fresh)	LC, UV	54 $\text{mg l}^{-1}$ (mean)
	Human milk (pasteurized)	LC, UV	8.6 $\text{mg l}^{-1}$ (mean)
	Lemon	Chemical	40–60 mg per 100 g
	Potato	Chemical	4–30 mg per 100 g
	Black currant	LC, UV	200–300 mg per 100 g
TPP	Human blood	LC, FL	120 $\text{nmol l}^{-1}$ (mean)
Thiamin (total)	Human blood	LC, FL	80–160 $\text{nmol l}^{-1}$
	Human milk	Chemical	0.01 mg per 100 g
	Cow's milk	Chemical	0.04 mg per 100 g
	Pork fillet	Chemical	1.1 mg per 100 g
	Brewer's yeast	Chemical	15.6 mg per 100 g
Riboflavin (total)	Human urine	LC, FL	40–350 $\mu\text{g}$ per g of creatinine
	Human blood	LC, FL	185 $\text{nmol l}^{-1}$ (mean)
	Cow's milk	LC, FL, or UV	0.1–0.16 mg per 100 g
	Cereals	LC, FL	0.1–1.1 mg per 100 g
	Wheat germ	Chemical	0.6–0.8 mg per 100 g
Nicotinic acid	Coffee	Chemical	10–30 mg per 100 g
Niacin, nicotinamide	Yeast	Chemical	50 mg per 100 g
	Wheat bran	Chemical	9–35 mg per 100 g
MNA	Human urine	LC, UV	31 $\mu\text{mol}$ per 24 h (mean)
2-Pyr	Human urine	LC, UV	60 $\mu\text{mol}$ per 24 h (mean)
Pantothenic acid	Human blood	Radioimmunoassay	1–2 $\text{mg l}^{-1}$
	Human urine	Radioimmunoassay	1–7.5 mg per 24 h
	Baker's yeast	Chemical	5–20 mg per 100 g
	Animal liver	Chemical	4–10 mg per 100 g
	Cow's milk	Chemical	0.3–0.4 mg per 100 g

<sup>a</sup>Abbreviations: TPP, thiamin pyrophosphate; MNA, *N*<sup>1</sup>-methylnicotinamide; 2-Pyr, *N*<sup>1</sup>-methyl-2-pyridone-5-carboxamide; PLP, pyridoxal-5'-phosphate; LC, liquid chromatography; UV, ultraviolet detection; FL, fluorescence detection; CPB, competitive protein-binding assay.

thiochrome method is as low as 50 fmol. In the area of folate analysis, tetrahydrofolate, 5-formyltetrahydrofolate, and 5-methyltetrahydrofolate can be determined at picomole levels by detecting their

native fluorescence. Folic acid itself must be converted to a fluorescent pterin derivative by a postcolumn reaction. Similarly, weakly fluorescent B<sub>6</sub> vitamins (pyridoxine, pyridoxal, pyridoxamine) can be oxidized

or converted to their semicarbazone, bisulfite, or hydroxysulfonate derivatives, which are fluorescent in an alkaline and neutral pH, respectively. Fluorescence detection is exemplified in Figure 1 for thiamin (as thiochrome) and riboflavin.

Electrochemical detection in LC provides a sensitive assay method for certain vitamins, such as AA, folates, and flavins. AA may be easily detected with femtomolar sensitivity. Sample preparation and matrix interference problems limit the routine applicability of electrochemistry in the analysis of water-soluble vitamins currently to AA.

Compared to LC, GC is currently less popular in routine vitamin analysis. The polar nature and low volatility of the water-soluble vitamins along with the heat lability of some vitamins hamper analysis by direct GC, making prior derivatization mandatory. GC has been used for the analysis of thiamin, niacin, pyridoxine, cobalamins, biotin, pantothenate, and AA, and for folate derivatives, especially with respect to stable isotope labeled probes. Most GC assays have been applied to relatively simple and pure samples such as multivitamin preparations. Only a few methods have been described for the determination of water-soluble vitamins in complex matrices such as foods and biological samples. A combination of GC with MS has been used in studies on the metabolism of pyridoxine, folate, and some other vitamins. This combination, although expensive in terms of instrumentation, holds promise as a reference method in the analysis of vitamins and their vitamers. The applicability of other analytical techniques could be verified using such a reference method. The main advantages of GC-MS, especially of the isotope dilution MS technique, include high sensitivity, precision, and accuracy of the quantitative measurement. The sample preparation prior to analysis may be more complicated than, for example, LC analysis, and the instrumentation is expensive. Very recently, tandem mass spectrometry and capillary electrophoresis have emerged as useful separation procedures for the highly sensitive analysis of some vitamins in 'difficult' biological matrices.

### Immunological Methods

Immunoassays, specific protein-binding assays, and radioisotope tests are sometimes used for the determination of water-soluble vitamins. These are the only feasible and practical methods for the quantification of certain vitamins in physiological samples. The principle of competitive protein binding (CPB) using labeled radioactive or fluorescent tracer is still routinely applied to quantification of serum vitamin

B<sub>12</sub> and folate, and erythrocyte folate. The assay for folate utilizes binding proteins from milk ( $\beta$ -lactoglobulin) and labeled folic acid (usually [<sup>125</sup>I] or fluorescence-labeled folic acid), which competes with the endogenous folate for the limited amount of binder. In this analysis, endogenous conjugase is allowed to cleave naturally occurring folyl-polyglutamates to monoglutamates, often in the presence of AA, this cleavage being necessary since the polyglutamates have a higher affinity for the binder and can thus degrade the accuracy of the assay. Moreover, the C<sub>1</sub> substituent of folates and the reduction status of the pyrazine ring also have an effect on the affinity for the binder. This assay can quantitatively measure folate at a concentration  $<1 \text{ nmol l}^{-1}$ . In clinical analyses the folate assay in erythrocytes may be favored, since it can reflect long-term folate status better than serum folate status does. Assay using CPB of serum cyanocobalamin is based on competition between the nonlabeled vitamin of the sample and the labeled vitamin (usually [<sup>57</sup>Co]cyanocobalamin or a fluorescent derivative) for a known amount of a specific binder, which usually is the intrinsic factor (IF). The sensitivity of this assay is  $\sim 20 \text{ pmol l}^{-1}$ . These two binding assays have also been combined in the form of a commercially available 'dual assay', in which the radioactive binders have been attached to an easily separable polymer. After incubation, the bound and free radioactivity are separated, and the radioactivity of the sediment is measured using the decay energies of iodine-125 and cobalt-57. With the aid of calibration graphs, the concentrations of these vitamins in serum can be calculated. More recently, fluorescence assays, which avoid the hazards of radioactive tracers, have tended to replace these radioassays.

Pyridoxine has been determined by using an enzymatic immunoassay, in which free vitamin competes with enzyme-labeled vitamin (pyridoxal- $\beta$ -galactosidase) for binding with antipyridoxal antibodies. Binding of the enzyme-labeled vitamin inhibits the enzymatic activity of  $\beta$ -galactosidase, while increasing amounts of the standard pyridoxamine leads to increasing enzyme activity. The vitamin concentration in the sample can then be extrapolated from a calibration graph. The detection limit of assay is  $\sim 50 \text{ nmol l}^{-1}$ . Two apparent problems with the method are cross-reactivity with other B<sub>6</sub> vitamers, the need to develop different antibodies against the various vitamers. Reactivation of tyrosine decarboxylase apoenzyme has been used as an assay for pyridoxal phosphate, and in recent years HPLC-fluorescence assays for vitamin B<sub>6</sub> co-enzymes have become the preferred choice.

Radioimmunoassay has been used for assay of pantothenic acid in physiological samples (sensitivity  $250 \text{ nmol l}^{-1}$ ), and an enzyme-linked immunosorbent assay (ELISA) has been used for this vitamin in food analysis.

## Examples and Limitations of Current Methodology

Table 4 summarizes some of the results obtained by the various methods of the determination of water-soluble vitamins in foods and physiological samples. In the past, biological, microbiological, and physico-chemical methods were widely used. Unfortunately, many of these methods are tedious and cumbersome, and too insensitive and/or nonspecific especially for clinical analyses. One practical problem with biological methods is related to their standardization: cells and microbes are able to utilize vitamins and/or co-enzymes at varying rates. However, these methods are feasible for selected purposes, e.g., in food analysis. Immunological methods are not very appropriate for vitamins. This is partly due to differences found in vitamins in cross-reactions against antibodies. Specific isotope-dilution competitive protein-binding methods, however, are usable at least for biotin, folate, and cyanocobalamin.

Chromatographic methods, especially LC, have offered increased selectivity and sensitivity in vitamin assays. This is reflected in the many methodological publications on the topic over the past decades. Analyses for water-soluble vitamins in physiological samples are now performed routinely using these methods. The problems with these methods are related to sample preparation and to the sensitivity of the detection method that is used. Only a few chromatographic methods enable simultaneous assay of several water-soluble vitamins in physiological samples, and so separate assays are needed. Less complex samples (e.g., pharmaceuticals or fortified foods) are easier to analyze in this respect.

As with all modern analytical programs, an essential keystone for success is a sound analytical quality control and assessment strategy, which should always, where possible, include the exchange of samples between different analytical laboratories and the use of round-robin external quality assurance schemes. External schemes for folate and cobalamins are already in existence in several countries; some other water-soluble vitamin assays are performed regularly by a sufficient number of different laboratories for external sample exchange schemes to be feasible and cost-effective, while others are too specialized and perhaps too rarely performed for regular

exchange schemes to be feasible; hence in these cases, ad hoc arrangements between participating laboratories is the only realistic option. In addition, the analyst should take care to ensure that the biological samples are stored under the optimal conditions for their maximal long-term stability, which usually means deep-freeze temperatures of  $-80^{\circ}\text{C}$  or below, possibly also with the addition of a stabilizing agent like freshly prepared metaphosphoric acid for vitamin C assay samples or AA for folate assay samples. Sample collections and 'banks' are now being prepared in conjunction with large-scale epidemiological studies in several countries for the future analysis of disease-predictive analytes, which may well include vitamins (e.g., EPIC, BIOBANK in Europe, including the UK), and it is critically important to ensure that such priceless sample collections are optimally collected and stored for a robust interpretation of future analytical programs.

## Introduction

Cyclic voltammetry involves scanning the potential applied to a working electrode according to triangular waveform and monitoring the resulting current flow. The current response provides a powerful and direct insight into the energetics of redox reactions, the dynamics and reversibility of the electron transfer, as well as the rates of coupled chemical reactions. It is the most commonly used electrochemical technique by both the electrochemical specialist and nonspecialist alike. Experimentally, the potential of a working electrode is cycled between two potential limits, driving the successive oxidation and reduction of an electroactive species that can be in solution or adsorbed at the electrode surface. By monitoring the current as a function of potential, current–potential voltammograms can be obtained that are unique to the system under study. Cyclic voltammetry has found applications in areas as diverse as elucidating complex reaction mechanisms and quantifying key environmental, industrial, and medical analytes in solution. In recent years, with the advent of more powerful instruments and microelectrodes, it has been possible to routinely measure the rapid rates of individual electron transfer reactions and even to identify species that exist for just a few nanoseconds using cyclic voltammetry!

In this article, the potential waveform employed to run cyclic voltammetry experiments is first described. The current–voltage waveforms for both reversible and irreversible redox reactions are then presented with an emphasis on the various parameters of

interest that can be extracted from cyclic voltammograms. Finally, some modern applications of the technique are outlined, such as monitoring heterogeneous electron transfer dynamics across the electrode/solution interface and investigation of redox reactions with following chemical reactions.

## Potential Sweep and Current Responses

The triangular potential waveform employed in cyclic voltammetry is shown in **Figure 1**. Typically, the potential is ramped linearly from an initial potential,  $E_i$ , to the switching potential,  $E_{\max}$ . The direction of the potential sweep is then reversed and scanning continues until  $E_{\min}$  is reached. The potential sweep may be terminated at the end of the first cycle or it may continue for an arbitrary number of cycles. The primary experimental parameters are the initial potential, the switching potentials, and the potential sweep rate. Typical sweep rates for cyclic voltammetry, employing electrodes of conventional sizes (e.g.,

**Figure 1** Triangular potential waveform employed in cyclic voltammetry.  $E_{\max}$  and  $E_{\min}$  are the switching potentials;  $t_s$  is the switching time;  $E_i$  is the initial potential.

disk electrodes of radii 1–2 mm) are in the range 1–1000 mV s<sup>-1</sup>. However, the accessible range of experimental sweep rates may be extended to the megavolt per second range by the use of microelectrodes.

The current response for an electroactive species in solution that can be reversibly reduced and reoxidized is shown in **Figure 2**. The initial potential is 0.7 V. Initially, no current flows at the working electrode. As the potential is scanned in a negative potential direction, the potential of the working electrode reaches a sufficiently negative value to cause a reduction of the redox species adjacent to the working electrode surface ( $\sim 0.5$  V). This causes a cathodic current, associated with reduction of the oxidized form of the analyte, to flow which increases rapidly as the surface concentration of oxidized species becomes zero. A diffusion-controlled cathodic current flows at the working electrode as oxidized material diffuses to the electrode surface and becomes reduced. The diffusion-controlled current peaks at  $\sim 0.32$  V and as the potential is scanned to more negative potentials the diffusion layer at the electrode surface becomes depleted of oxidized material. This depletion causes a decrease in the rate of reduction of material at the electrode and a resultant decay in the cathodic current. At potentials negative of 0.32 V, the current decays with  $t^{-1/2}$  according to the Cottrell equation.

At the switching potential, 0 V, the potential sweep is reversed and the potential remains sufficiently negative to cause a reduction reaction at the electrode surface. This small cathodic current continues until the working electrode potential becomes

sufficiently positive to cause oxidation of the reduced species adjacent to the electrode surface ( $\sim 0.25$  V). This causes a diffusion-controlled anodic current to flow, which increases until depletion of reduced material occurs and the anodic current peaks at  $\sim 0.38$  V. The anodic current then decays with  $t^{-1/2}$  as the diffusion layer is depleted of the reduced species. As the potential returns to the initial potential (0.7 V), a small anodic current still flows as the reduced species diffuses to the electrode surface and is oxidized. In the cyclic voltammogram, important quantitative parameters of interest are the cathodic and anodic peak potentials ( $E_{p,c}$  and  $E_{p,a}$ ), the magnitudes of the cathodic and anodic peak currents ( $i_{p,c}$  and  $i_{p,a}$ ), the difference between the cathodic and anodic peak potentials ( $\Delta E_p = |E_{p,a} - E_{p,c}|$ ), the potential at half-height of the peak ( $E_{p/2} = E$  at  $i = i_{p/2}$ ), and the redox formal potential ( $E^{\circ'} = [E_{p,a} + E_{p,c}]/2$ ).

## Reversible (Nernstian) Behavior

For a reversible system in which an oxidized species is reduced with the transfer of  $n$  electrons, the voltammetric peak current (in amperes) at 298 K is given by the Randles–Sevcik equation:

$$i_p = (2.69 \times 10^5) n^{3/2} A D^{1/2} C v^{1/2} \quad [1]$$

where  $A$  is the electrode area (cm<sup>2</sup>),  $D$  is the diffusion coefficient (cm<sup>2</sup> s<sup>-1</sup>),  $C$  is the bulk concentration of the oxidized species, and  $v$  is the potential sweep rate (V s<sup>-1</sup>).

A common diagnostic of a reversible system is the difference between  $E_p$  and  $E_{p/2}$ :

$$|E_p - E_{p/2}| = 2.2 \frac{RT}{nF} = \frac{56.5}{n} \text{ mV} \quad [2]$$

where  $R$  is the gas constant (8.314 J K<sup>-1</sup> mol<sup>-1</sup>),  $T$  is the temperature (K), and  $F$  is the Faraday constant ( $9.6485 \times 10^4$  C mol<sup>-1</sup>). The peak potential difference,  $\Delta E_p$ , depends on the value of the switching potential relative to the peak potential. When the switching potential exceeds the peak potential by an infinite amount,  $\Delta E_p$  is equal to 57/ $n$  mV.  $\Delta E_p$  increases slightly as the difference between the peak and switching potentials decrease. For example, when the switching potential is 71.5 mV past  $E_p$ ,  $\Delta E_p$  is 60.5 and when the potential is switched 121.5 mV past the peak potential,  $\Delta E_p$  equals 59.2/ $n$  mV.

Thus, for a reversible (Nernstian) process,  $i_p$  is proportional to  $v^{1/2}$ ,  $E_p$  is independent of  $v$ ,  $|E_p - E_{p/2}|$  is 56.5/ $n$  mV,  $\Delta E_p$  is  $\sim 57$  mV, and  $|i_{p,c}/i_{p,a}|$  is 1.

**Figure 2** Cyclic voltammogram for a reversible, one-electron redox reaction.

## Irreversible Behavior

For a completely irreversible system involving the reduction of an oxidized species with the transfer of one electron, the peak current in amperes at 298 K is

$$i_{p,c} = (2.99 \times 10^5) \alpha^{1/2} A C D^{1/2} v^{1/2} \quad [3]$$

where  $\alpha$  is the transfer coefficient and is related to the shape of the energy barrier to electron transfer. As the redox reaction is completely irreversible, the cyclic voltammogram for this system only contains a cathodic wave and linear sweep and cyclic voltammetry will produce the same response.

The difference between the peak potential and the potential at half the peak height is given by

$$|E_p - E_{p/2}| = 1.847 \frac{RT}{\alpha F} = \frac{47.7}{\alpha} \text{ mV at } 25^\circ\text{C} \quad [4]$$

For a completely irreversible wave,  $E_p$  will shift in a negative (for a reduction reaction) potential direction with increasing sweep rate.

## Cyclic Voltammetry of Surface Confined Species

The typical cyclic voltammogram for a redox reaction involving a surface confined, monomolecular layer of a redox species is shown in Figure 3. Both the anodic and cathodic waves are entirely symmetrical across the potential axis and the peak current for the cathodic and anodic reactions is given by

$$i_p = \frac{n^2 F^2}{4RT} v A \Gamma \quad [5]$$

**Figure 3** Cyclic voltammogram for a surface confined, one-electron redox reaction.

where  $\Gamma$  is the surface coverage of electroactive species in moles per square centimeter.

This voltammetric behavior is also observed for thin films (multilayers) of electroactive material at electrode surfaces provided that the experimental timescale is sufficiently long (i.e., slow scan rates). Under these conditions, such a thin layer of redox-active species is exhaustively electrolyzed, finite diffusion predominates, and the voltammetric response will be similar to that shown in Figure 3.

For an immobilized film of electroactive species, the peak current is proportional to  $v$ , rather than the  $v^{1/2}$  dependence observed for freely diffusional species. The area under the wave represents the charge passed during electrolysis of the film and is given by

$$Q = nFA\Gamma \quad [6]$$

A useful insight into the extent of lateral interactions between adsorbates may be obtained from the full-width at half-maximum (FWHM), i.e., the total width of the anodic or cathodic wave at half the peak current. Under Langmuir isotherm conditions (i.e., when there are no interactions between adjacent adsorbates), the FWHM for an ideal Nernstian reaction at 298 K is given by

$$\text{FWHM} = 3.53 \frac{RT}{nF} = \frac{90.6}{n} \text{ mV} \quad [7]$$

Deviations from this value can indicate the presence of attractive ( $< 90.6/n$  mV) or repulsive ( $> 90.6/n$  mV) interactions between adjacent adsorbates.

The formal potential,  $E^{\circ'}$ , contains extremely useful information about the ease of oxidation of redox species within a surface confined film. A shift of  $E^{\circ'}$  of an electroactive species, upon immobilization at an electrode surface, toward more positive potentials indicates that it becomes thermodynamically more difficult to oxidize the film. This suggests a reduced electron density on the redox centre when immobilized.

## Microelectrodes

One of the key barriers to the more widespread adoption of voltammetric techniques was the limited range of media in which analysis could traditionally be performed, i.e., aqueous solutions containing a relatively high concentration of supporting electrolyte. This restriction arose because resistance between the working or sensing electrode and the reference electrode limited the precision with which the applied potential could be controlled. However, microelectrodes, also commonly known as ultra-microelectrodes, whose critical dimension is in the

micrometer range open up new dimensions of space, time, and medium for electroanalysis. The currents observed at microelectrodes typically lie in the picoampere to nanoampere range, which are several orders of magnitude smaller than those observed at conventional millimeter dimensioned macroelectrodes. These small electrolysis currents often completely eliminate ohmic effects. Thus, electrochemical processes can be investigated in high resistance solvents, in solids, in supercritical fluids, and in gases. Moreover, they facilitate measurements at short timescales and at low temperatures.

### Reduced Ohmic Effects

When Faradaic and charging currents flow through a solution, they generate a potential that acts to diminish the applied potential by an amount  $iR_u$ , where  $i$  is the total current and  $R_u$  is the uncompensated cell resistance. This is an undesirable process that leads to distorted voltammetric responses.

The uncompensated solution resistance for a disk-shaped microelectrode is inversely proportional to the electrode radius,

$$R_u = \frac{1}{4\kappa r_0} \quad [8]$$

where  $\kappa$  is the conductivity of the solution and  $r_0$  is the radius of the microdisk. Equation [8] shows that  $R_u$  ‘increases’ as the electrode radius ‘decreases’. However, the currents observed at microelectrodes are typically six orders of magnitude smaller than those observed at macroelectrodes. These small currents often completely eliminate ohmic drop effects even when working in organic solvents. For example, the steady-state current observed at a 5  $\mu\text{m}$  radius microdisk is  $\sim 2 \text{ nA}$  for a  $1.0 \text{ mmol l}^{-1}$  solution of ferrocene in acetonitrile. Taking a reasonable value of  $0.01 \Omega^{-1} \text{ cm}^{-1}$  as the specific conductivity, eqn [8] indicates that the resistance will be of the order of  $50\,000 \Omega$ . This analysis suggests that the  $iR_u$  drop in this organic solvent is a negligible 0.09 mV. In contrast, for a conventional macroelectrode the  $iR_u$  drop would be  $\sim 5\text{--}10 \text{ mV}$ . Under these circumstances, distorted current responses and shifted peak potentials are observed in cyclic voltammetry.

### Capacitive Effects

Altering the potential that is applied to an electrode causes the charge on the metal side of the interface to change and some reorganization of the ions and solvent dipoles in the double layer on the solution side of the interface will occur. This process causes electrons to flow into or out of the surface, giving rise to a charging or capacitive response. The double

layer capacitance for a disk-shaped microelectrode is proportional to the area of the electrode surface and is given by

$$C_{dl} = \pi r_0^2 C_0 \quad [9]$$

where  $C_0$  is the specific double layer capacitance of the electrode. Thus, shrinking the size of the electrode causes the interfacial capacitance to decrease with decreasing  $r_0^2$ . These low capacitive currents are particularly important for analytical applications of cyclic voltammetry where the ability to discriminate a Faradaic signal above a charging current often dictates the limit of detection that can be achieved.

### Mass Transport

A distinct advantage of microelectrodes over larger electrodes is that a range of diffusional mass transport regimes can be observed at timescales that can be easily accessed experimentally. As discussed previously, oxidation or reduction of an electroactive species at the surface of a relatively larger electrode ( $\text{mm}^2$ ) at relatively fast scan rates ( $100 \text{ mVs}^{-1}$ ) causes a diffusional current to flow that peaks at  $E_p$ , after which depletion of electroactive materials occurs and the current decays. However, the timescale of the experiment significantly affects the diffusional mass transport regime and significantly influences the response observed. By examining the time dependence of the diffusional mass transport process it is possible to predict the cyclic voltammetry response and extract quantitative electroanalytical information.

For example, consider a spherical electrode of radius  $r_0$  placed in a solution that contains only supporting electrolyte and a redox-active species at concentration  $C$ . The concentration gradient at the electrode surface after applying a potential step to the electrode is obtained by solving Fick’s second law in spherical coordinates:

$$\frac{\partial C(r, t)}{\partial t} = D \left[ \frac{\partial^2 C(r, t)}{\partial r^2} + \frac{2}{r} \frac{\partial C(r, t)}{\partial r} \right] \quad [10]$$

The boundary conditions for the potential step experiment are

$$\lim_{r \rightarrow \infty} C(r, t) = C^\infty \quad [11]$$

$$C(r, 0) = C^\infty \quad [12]$$

$$C(r_0, t) = 0 \quad [13]$$

where  $r$  is the distance from the center of the sphere,  $r_0$  is the radius of the electrode,  $D$  is the diffusion coefficient for the redox active species, and  $C$  is the concentration as a function of distance  $r$  and time  $t$ .

Equation [10] can be solved using Laplace transform techniques to give the time evolution of the current,  $i(t)$ , subject to the boundary conditions described resulting in eqn [14]:

$$i(t) = \frac{nFADC^\infty}{r_0} + \frac{nFAD^{1/2}C^\infty}{\pi^{1/2}t^{1/2}} \quad [14]$$

Equation [14] reveals that the current contains both time-dependent and -independent terms. The differences in the electrochemical responses observed at macroscopic and microscopic electrodes arise because of the relative importance of these terms at conventional electrochemical timescales. It is possible to distinguish two limiting regimes depending on whether the experimental timescale is short or long.

**Short times** At sufficiently short times, the thickness of the diffusion layer that is depleted of reactant is significantly smaller than the electrode radius and the spherical electrode appears to be planar to a molecule at the edge of this diffusion layer. Under these conditions, the electrode behaves like a macroelectrode and mass transport is dominated by linear diffusion to the electrode surface as illustrated in **Figure 4A**. At short times the first part of eqn [14] becomes insignificant compared to the second part due to the  $t^{-1/2}$  dependence of the current. Therefore, the current decays over time in accordance with the Cottrell equation:

$$i(t) = \frac{nFAD^{1/2}C^\infty}{\pi^{1/2}t^{1/2}} \quad [15]$$

**Long times** At long times (i.e., slow scan rates), the second term in eqn [14] becomes negligible and the current attains a time-independent steady-state value given by eqn [16]:

$$i_{ss} = \frac{nFADC^\infty}{r_0} \quad [16]$$

At these long times, the spherical character of the electrode becomes important and the mass transport process is dominated by radial (spherical) diffusion as illustrated in **Figure 4B**.

**Figure 5A** shows the sigmoidal-shaped responses that characterize steady-state mass transfer in slow scan-rate cyclic voltammetry. In contrast, as illustrated in **Figure 5B**, at short experimental timescales (high scan rates), peaked responses similar to those observed at conventional macroelectrodes are seen.

The preceding analysis considered a spherical electrode because its surface is uniformly accessible, and a simple closed-form solution to the diffusion equation exists. The microdisk is the most widely used geometry, but derivation of rigorous expressions describing their experimental response is complicated because the surface is not uniformly accessible. For disks, electrolysis at the outer circumference of the disk diminishes the flux of the electroactive material to the center of the electrode. However, microdisk and microring geometries share the advantage of spherical microelectrodes in that quasispherical diffusion fields are established in relatively short periods of time. The steady-state current is given by

$$i_{ss} = \gamma nFDCr_0 \quad [17]$$

**Figure 5** Effect of scan rate on the cyclic voltammetry of  $1.0 \text{ mol l}^{-1}$  ferrocene at a  $6.5 \mu\text{m}$  gold microdisk where the supporting electrolyte is  $0.1 \text{ mol l}^{-1}$  tetrabutyl ammonium perchlorate in acetonitrile: (A) scan rate is  $0.1 \text{ V s}^{-1}$ ; (B) scan rate is  $10 \text{ V s}^{-1}$ .

**Figure 4** Diffusion fields observed at microelectrodes: (A) linear diffusion observed at short times; (B) radial diffusion observed at long times.

where  $\gamma$  is 4 and  $2\pi$  for disk and hemispherical shaped electrodes, respectively.

## Electroanalysis

Voltammetry provides both qualitative and quantitative analytical information about the concentration of redox-active species within samples as diverse as foods, polymers, beverages, drugs, fine chemicals, cosmetics, plating baths, animal feed, raw materials, water, and wastewater. Versatility and simplicity distinguish the technique and the following list highlights some of the main advantages:

- sensitivity,
- speed,
- speciation,
- multicomponent capability,
- versatility,
- response immune to colored or turbid samples, and
- reliability.

As illustrated in Figure 6, a wide range of elements can be analyzed using cyclic voltammetry and this breadth of application is dramatically expanded when one considers the diverse range of inorganic and organic species that is electroactive. Cyclic voltammetry provides routine analysis at low levels using instrumentation and consumables that are widely available at low cost. Also, a wide variety of methods have been developed that can allow complex mixtures to be analyzed often with a minimum

of cleanup. For example, by correlating the formal potentials of unknown components within mixtures with reference compounds it may be possible to identify unknowns within complex mixtures. However, this approach is limited since the experimental response for a single analyte takes up a significant fraction of the available analytical window. While techniques such as differential pulse voltammetry offer significantly greater sensitivity, voltammetry is capable of measuring concentrations at ppb levels.

## Heterogeneous Electron Transfer Dynamics

Beyond an insight into the ease with which compounds can be oxidized or reduced by measuring the formal potential, cyclic voltammetry can be used to determine the rate of electron transfer across the electrode/solution or electrode/film interface. Optimizing the rate of heterogeneous electron transfer is important for technological applications ranging from the analysis of metals in polymers, foods, and cosmetics to the development of biosensors and molecular electronic devices.

Electrolysis (oxidation or reduction) of a freely diffusing electroactive species at an electrode surface during cyclic voltammetry consists of a number of elementary steps. Initially, diffusion of the redox species to the electrode surface under the influence of a concentration gradient must occur. Thermal activation of the redox center and electronic coupling of the activated redox center with the electrode

**Figure 6** Elements capable of being analyzed using voltammetry at mercury electrodes (elements in the shaded region).

surface must then occur. Finally, the instantaneous elementary electron transfer event occurs. In investigating heterogeneous electron transfer dynamics, one must ensure that the rate of mass transfer to the electrode surface exceeds the rate of electron transfer, for example, by stirring the solution, rotating the electrode, or by using microelectrodes.

Research into this area is dominated by microelectrodes. At short times, the diffusion layer thickness is much smaller than the microelectrode radius and the dominant mass transport mechanism is planar diffusion. Under these conditions, the classical theories, e.g., that of Nicholson and Shain, can be used to extract kinetic parameters from the scan rate dependence of the separation between the anodic and cathodic peak potentials. Using this approach, the standard heterogeneous electron transfer rate constant,  $k^\circ$ , may be determined from the published working curves relating  $\Delta E_p$  to a kinetic parameter  $\Psi$ . The variation of  $\Delta E_p$  with  $\nu$  is determined and, from this,  $\Psi$  is calculated.  $k^\circ$  is then determined by the following equation:

$$k^\circ = \Psi \left[ D_0 \pi \nu \left( \frac{nF}{RT} \right) \right]^{1/2} \left( \frac{D_R}{D_O} \right)^{\alpha/2} \quad [18]$$

However, this approach can be limited due to factors such as convolution of Faradaic and charging currents at high scan rates. In addition, uncompensated ohmic effects at high scan rates may result in inaccurate measurements of heterogeneous electron transfer kinetics. One particular approach that can overcome these limitations is to simulate the entire cyclic voltammogram. In addition to this, positive feedback circuitry can be used to compensate for Ohmic drop. This approach has been used successfully for a wide range of organic and inorganic compounds and Figure 7 shows an example of a comparison between a simulated and experimental

voltammogram. By simulation of the entire voltammogram, the standard heterogeneous electron transfer rate constant,  $k^\circ$ , has been determined as  $5.1 \text{ cm s}^{-1}$  for the ferrocene/ferrocenium redox couple.

An attractive approach to solving the mass transfer limitations of these investigations is to immobilize the electroactive species at the electrode surface within a monomolecular film. Clearly, if the electroactive species is immobilized at the electrode surface, diffusion of the species to the electrode does not need to occur prior to electron transfer. In addition, immobilization at an electrode surface can preconcentrate the species of interest, resulting in higher currents that are easier to detect. Electroactive adsorbed monolayers have been developed that exhibit close to ideal reversible electrochemical behavior under a wide variety of experimental conditions of timescale, temperature, solvent, and electrolyte. These studies have elucidated the effects of electron transfer distance, tunneling medium, molecular structure, electric fields, and ion pairing on heterogeneous electron transfer dynamics.

## Following Chemical Reactions

Beyond the ability to probe heterogeneous electron transfer reactions that occur on the micro, or even nano timescale, high-speed cyclic voltammetry has found application in the investigation of complex reaction mechanisms. An example of this is the following chemical (EC) reaction. The oxidation or reduction (E reaction) of an electroactive species can produce a chemically unstable product that undergoes a chemical reaction (C reaction) to form an electroinactive product. Electron transfer reactions can also lead to isomerizations and ligand loss in organometallic compounds, such as

**Figure 7** Background-subtracted experimental (solid lines) and simulated (open circles) cyclic voltammograms for a solution of ferrocene ( $10 \text{ mmol l}^{-1}$ ) in acetonitrile containing  $0.6 \text{ mol l}^{-1}$  TEAP. Sweep rates are 100, 200, and  $500 \text{ kV s}^{-1}$  and the gold microelectrode radius is  $5 \mu\text{m}$ . Simulations allow for ohmic drop and RC constant and  $k^\circ$  is  $3.1 \text{ cm s}^{-1}$ . ## Introduction

Linear sweep voltammetry (LSV) and cyclic voltammetry (CV) are the most widely used voltammetric techniques for studying redox reactions of both organic and inorganic compounds because they are unmatched in their ability to provide information on the steps involved in electrochemical processes

with only a modest expenditure of time and effort in the acquisition and interpretation of data. These electroanalytical methods require simple and inexpensive instrumentation and provide not only information on the electrochemical quantities typical of a redox process, but also allow investigations of chemical reactions coupled with charge transfer steps. This is because the electrode can be used as a tool for producing reactive species in a small solution layer surrounding its surface and at the same time to monitor chemical reactions involving these species. Moreover, since the relevant responses can be obtained within a few milliseconds after stimulation of the

**Figure 8** (A) First three sweeps of a voltammogram for an EC reaction at a scan rate of  $0.2 \text{ V s}^{-1}$ . (B) Voltammogram for the same system as in (A) at a scan rate of  $50 \text{ V s}^{-1}$ .

where en is ethylenediammine. Figure 8A shows a slow scan rate ( $0.2 \text{ V s}^{-1}$ ) cyclic voltammogram for an EC reaction:

where the reduced product, B, undergoes a reaction to form C, which is electroinactive. The ratio of anodic peak current to cathodic peak current is less than 1. Figure 8B illustrates the same system while using a sweep rate of  $50 \text{ V s}^{-1}$ . The smaller timescale of the voltammogram in Figure 8B illustrates the ability of higher sweep rate cyclic voltammetry to outrun the following chemical reaction.

## Linear Sweep and Cyclic

## Introduction

Linear sweep voltammetry (LSV) and cyclic voltammetry (CV) are the most widely used voltammetric techniques for studying redox reactions of both organic and inorganic compounds because they are unmatched in their ability to provide information on the steps involved in electrochemical processes

with only a modest expenditure of time and effort in the acquisition and interpretation of data. These electroanalytical methods require simple and inexpensive instrumentation and provide not only information on the electrochemical quantities typical of a redox process, but also allow investigations of chemical reactions coupled with charge transfer steps. This is because the electrode can be used as a tool for producing reactive species in a small solution layer surrounding its surface and at the same time to monitor chemical reactions involving these species. Moreover, since the relevant responses can be obtained within a few milliseconds after stimulation of the

electrode, they may be used for studying mechanisms involving very fast reactions, thus allowing detection of short-lived transient intermediates.

LSV and CV techniques were proposed at the beginning of the 1950s and in those years some theoretical approaches able to rationalize the simplest responses were worked out. However, the use of these electroanalytical methods has received considerable impetus only recently thanks to increased knowledge of more subtle criteria for interpreting the relevant responses and to greater availability of theoretical tools for processing experimental data.

This article will briefly survey the analytical performance of these techniques, as well as the criteria followed to gain information regarding participants in electrochemical processes from the recorded responses.

## Fundamentals

In both LSV and CV, a small ( $<0.1 \text{ cm}^2$ ) stationary working electrode is dipped in an unstirred solution containing an excess of supporting electrolyte to repress migration of charged reactants and products, so that any transfer of electroactive species to and from the electrode surface can occur only through diffusion. In LSV, the potential of the working electrode is changed linearly with time, as shown in the upper plot of Figure 1A, starting from a potential where no

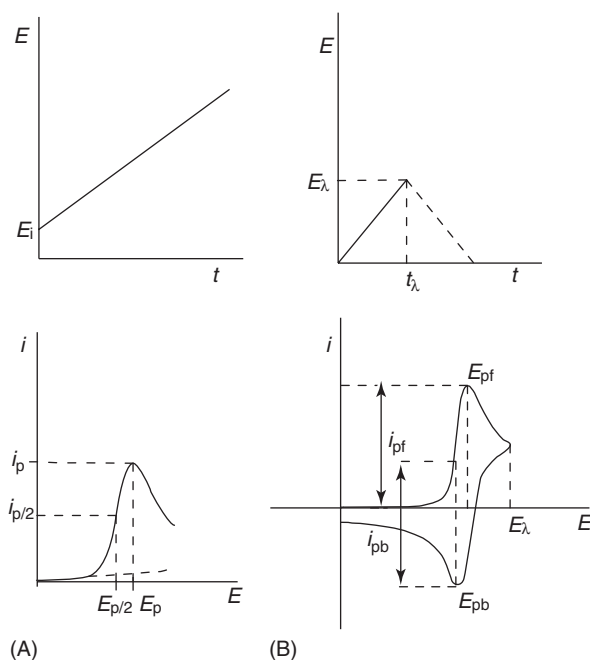

electrode reaction occurs and moving to potential where reduction (more negative values) or oxidation (more positive values) of the investigated analyte takes place, so that the instantaneous potential applied can be written as follows:

$$E_t = E_i \pm vt \quad [1]$$

where  $E_t$  is the electrode potential at time  $t$ ,  $E_i$  the starting potential, and  $v$  the scan (or sweep) rate, i.e., the absolute value of the rate of the potential change,  $dE/dt$ , which is constant within any sweep. The sign depends upon the potential scan direction (positive for anodic sweeps and negative for cathodic sweeps).

The current is measured throughout the experiment and the resulting current–potential curve (voltammogram) displays the typical shape shown in the lower plot in Figure 1A, also reporting main parameters. They are  $i_p$  = peak current, i.e., the maximum current value;  $E_p$  = peak potential, i.e., the potential corresponding to  $i_p$ ;  $E_{p/2}$  = half-peak potential, i.e., the potential at which  $i = i_p/2$ .

Peak position on the potential scale ( $E_p$ ), which is related to the formal potential of the redox process and to its reversibility degree (conditioning also the peak shape  $E_p - E_{p/2}$ ) gives information on the analyte involved. Conversely, peak height ( $i_p$ ) gives information on the analyte concentration, number of electrons involved in the electrochemical process, and possible presence of coupled chemical reactions. As long as the electrode potential is scanned in a region where no charge transfer occurs (from the starting potential  $E_i$  to the rising portion of the peak-shaped response), only a little capacitive current is recorded because the electrode–solution interphase behaves like a capacitor, whose capacitance depends on the electrode potential value because its change causes ions and molecules near the electrode to modify their orientation. On the contrary, when the potential attains the region where the electrochemical reaction occurs, a Faradaic current is recorded which increases sharply until a maximum is reached; thereafter the current decreases steadily. Such a peak shape comes out from the competition of the increase in the rate of the electrode reaction as the potential is made more and more suitable for its occurrence (prevailing in the rising portion of the peak) with the increasing thickness of the diffusion layer due to the progressive depletion of the depolarizer at an increasing distance from the electrode surface (prevailing in the descending branch). Consequently, the peak current is recorded at a potential where these counteracting effects balance each other, i.e., when the analyte concentration at the electrode surface is not yet down to zero, so that  $E_p$  falls at potentials preceding those

**Figure 1** Potential waveforms for linear sweep (A), and cyclic (B) voltammetry and the resulting voltammograms.

proper for the limiting current region in conventional d.c. voltammetry.

The voltage waveform applied to the working electrode in CV is shown in the upper plot of **Figure 1B**. Before the switching time,  $t_\lambda$ , the electrode potential is varied linearly with time like in LSV, while at  $t_\lambda$  the potential scan direction is reversed, so that the waveform becomes the combination of two joined linear sweeps. The switching potential  $E_\lambda$  is in fact both the final potential for the forward scan and the initial potential for the reverse sweep. Consequently, the potential applied to the working electrode in the forward scan is once again described by eqn [1], while  $E_t$  for the backward scan ( $t_\lambda < t < 2t_\lambda$ ) is given by

$$E_t = E_i \pm vt_\lambda \mp v(t - t_\lambda) = E_i \pm 2vt_\lambda \mp vt \quad [2]$$

where upper signs refer to forward anodic sweeps and lower signs refer to forward cathodic sweeps. This equation applies to symmetrical triangular waveforms that are the most commonly adopted in CV, even though other waveforms have also been proposed. When this triangular waveform is used to investigate electrochemical processes involving oxidized and reduced forms both stable during the time required to record a voltammogram, the electrode reaction occurring in the backward scan involves the species electrogenerated in the forward sweep still present in the solution layer surrounding the electrode surface, so that the electrode reaction symmetrical to the onward reaction takes place. Consequently, as shown in the lower plot in **Figure 1B**, a backward peak is associated to the forward peak due to the renewal of the starting species. In agreement with the notation adopted above,  $i_{pf}$ ,  $i_{pb}$ ,  $E_{pf}$ ,  $E_{pb}$  (f, forward; b, backward) are defined in cyclic voltammograms.

In the rather small potential range where forward and backward reactions occur simultaneously, the current is the algebraic sum of a cathodic contribution and an anodic contribution. Therefore, for a correct evaluation of the backward peak-current a suitable baseline must be used to subtract the contribution of the forward electrode process. This contribution can be experimentally determined by extending the forward scan beyond the switching potential  $E_\lambda$ , until a potential  $E_x$  is reached so that  $E_x - E_\lambda = E_\lambda - E_{pb}$ , as shown in **Figure 2**. The use of this method is, however, precluded when further interfering electrode processes occur beyond  $E_\lambda$ , so that alternative procedures have been proposed, all based on the consideration that the current becomes purely diffusion controlled at a potential beyond enough the peak. Their applicability

**Figure 2** Baseline evaluation for the reverse scan in a cyclic voltammogram.

is, however, restricted to particular electrochemical processes with the exception of the following equation (the meaning of the symbols can be inferred from **Figure 2**) enabling the ratio  $i_{pb}/i_{pf}$  to be calculated directly from a single cyclic voltammogram:

$$\frac{i_{pb}}{i_{pf}} = \frac{(i_{pb})^\circ}{i_{pf}} + \frac{(i_\lambda/i_{pf}) \times \{1 + (E_{pb} - E_\lambda)\}}{[(i_1)^2 - (i_x)^2]/[(i_1)^2(E_1 - E_\lambda)]^{-1/2}} \quad [3]$$

Of course, when the charge transfer is so slow that the associated forward and backward responses are recorded in different potential regions, the baseline for the backward peak is given by the capacitive current alone, as reported above for the forward peak.

## Characterization of Electrochemical Processes

An electrochemical process occurs frequently through a sequence of steps including: (1) the transfer of both the reactant from the bulk of the solution to the electrode surface and the product in the opposite direction, (2) the charge transfer reaction, and (3) possible structural rearrangements and possible chemical reactions preceding, following, or parallel to the charge transfer step, as well as interposed between two subsequent charge transfers. Additionally, adsorption and other surface reactions may need to be considered. Voltammetric responses are affected by each of these steps to an extent depending on the

scan rate adopted, which markedly conditions the timescale of any experiment. Thus, an electron transfer may appear fast or slow and a coupled chemical reaction can or cannot occur, depending upon the potential sweep rate employed. Scan rates varying from few tens of  $\text{mV s}^{-1}$  to hundreds of  $\text{V s}^{-1}$  can be adopted and this favorable opportunity results in timescales (also controlled by the potential range traversed) in the range  $10^{-5}$ – $10^2$  s. In other words, the scan rate defines an experimental time-window through which the electrochemical process is seen, so that chemical reactions occurring significantly at slow enough scan rates become undetectable when  $\nu$  is increased and fast charge transfers can be seen as slow at high enough scan rates.

The effects caused by the main step of those mentioned are shortly reviewed in the following sections, considering first the electrochemical processes in which reactants, intermediates, and products are freely diffusing solution species, not interacting with the electrode surface.

### Uncomplicated Charge Transfer Processes

We first consider electrochemical processes involving sole charge transfers, uncoupled with chemical events or adsorption phenomena, i.e., simple heterogeneous reactions that may occur in the timescale of the experiment with either a very high rate (Nernstian or reversible behavior) or a finite rate (nonreversible behavior). In this last case, the process is defined totally irreversible when forward and backward reactions occur with an appreciable rate only in totally different potential ranges, while it is defined quasireversible when a finite potential range exists in which both forward and backward electrode reactions occur with an appreciable rate, thus affording currents that are the algebraic sum of the two contributions.

In LSV and CV, a redox system may show a Nernstian, quasireversible or totally irreversible behavior depending on the scan rate employed, since  $\nu$  determine the time available for the electrode-solution interphase to attain the equilibrium condition dictated by the Nernst equation. Such a dependence is usually rationalized by the following dimensionless parameter, comparing the standard heterogeneous rate constant  $k_{\text{sh}}$  with the scan rate  $\nu$ :

$$\Psi = \gamma^\alpha k_{\text{sh}} / (\pi a D_{\text{O}})^{1/2} \quad [4]$$

where  $\gamma = (D_{\text{O}}/D_{\text{R}})^{1/2}$  is the square root of the ratio between the diffusion coefficients of the oxidized ( $D_{\text{O}}$ ) and reduced ( $D_{\text{R}}$ ) species,  $\alpha$  is the charge transfer coefficient and  $a = nF\nu/RT$  (where  $n$  is the overall number of electrons involved in a charge transfer,

$F$  is Faraday's constant (charge on 1 mol of electrons) =  $96.487 \text{ (C mol}^{-1}\text{)}$ ,  $R$  is the ideal-gas constant =  $8.31 \text{ J}$  and  $T$  is the absolute temperature (K)) is the normalized scan rate (this definition of  $\Psi$  applies to reduction processes, while for oxidation reactions  $D_{\text{O}}$  is replaced by  $D_{\text{R}}$ ). On these bases, a charge transfer is defined reversible for  $\Psi > 7$ , quasireversible for  $7 > \Psi > 10^{-3}$ , and totally irreversible for  $\Psi < 10^{-3}$ . Consequently, the same redox system displays a reversible behavior for high enough  $\Psi$  values (low values of  $\nu$ , when the system is allowed a long time to attain equilibrium conditions), while it becomes totally irreversible at sufficiently high scan rates when  $\Psi < 10^{-3}$ , on passing through quasireversible conditions for intermediate  $\nu$ . Such a transition is shown in Figure 3 reporting the effect of  $\Psi$  on the response recorded for a one-electron redox system characterized by  $\alpha = 0.5$ .

Indeed, Figure 3 reports normalized current-potential plots, in order to make voltammograms independent of the experimental variables typical of the particular redox process considered. This is accomplished by replacing current with the dimensionless quantity  $\pi^{1/2}\chi(at)$ , i.e., a function of both  $a$  (scan rate) and  $t$  (potential), named current-function, whose generalized form is as follows:

$$\pi^{1/2}\chi(at) = i(at)/nFA(C_{\text{O}})^b(D_{\text{O}})^{1/2}a^{1/2}\alpha^{1/2} \quad [5]$$

where  $i(at)$  is the current,  $A$  is the electrode area,  $(C_{\text{O}})^b$  is the bulk concentration of the oxidized analyte, and other symbols have the meaning defined earlier. For reversible electrode reactions a unity value must be assigned in this equation to the charge

**Figure 3** Effect of the dimensionless parameter  $\psi$  on cyclic voltammetric responses for an uncomplicated one-electron system characterized by  $\alpha = 0.5$ . The starting species is the oxidized one. The x-axis represents the difference of electrode potential ( $E$ ) and standard potential ( $E^\circ$ ).

transfer coefficient  $\alpha$ , even though such a parameter is does not make sense in this particular case.

This current-function exhibits a maximum value (peak-current-function) of 0.4463 for reversible charge transfers and of 0.4958 for totally irreversible redox reactions, but the higher value for this last case must not be misleading, since the following peak-current ratio for these two limiting cases is inferred from eqn [5]:

$$(i_p)_{\text{irr}}/(i_p)_{\text{rev}} = (0.4958/0.4463)\alpha^{1/2} \quad [6]$$

When  $\alpha = 0.5$ , as frequently occurs, this peak-current ratio becomes 0.784, thus pointing out that higher peaks are found under the same experimental conditions for Nernstian charge transfers, in agreement with the progressive peak-lowering and peak-broadening accompanying the decrease of the apparent reversibility degree ( $\psi$ ) shown in Figure 3.

Finally, the linear dependence of the peak current on both the analyte concentration and square root of  $\nu$  must be emphasized. The dependence on the analyte concentration is the basis of the application of LSV to quantitative analysis, while the dependence on  $\nu^{1/2}$  suggests the possibility of modulating suitably the sensitivity of LSV and CV measurements.

Table 1 summarizes the parameters characterizing LSV and CV responses for the different types of uncomplicated charge transfers, as well as their trend with  $\nu$ , whose suitable use enables charge transfers to be characterized even by evaluating their typical quantities ( $k_{\text{sh}}$ ,  $\alpha$ , and  $E_{1/2}$ ).

### Coupled Chemical Reactions

Reactants and products of electrode processes may be involved in chemical reactions following, preceding, or parallel to electron transfers. These reactions affect voltammograms to an extent that depends on both their nature and their rate compared with the timescale of the experiment. In particular, voltammetric responses remain unaltered at scan rates so high as to prevent the occurrence of chemical reactions in the time span of the experiment. Conversely, chemical reactions occurring at higher rates than the potential scan result in potential shifts of voltammetric profiles, at least. When chemical-reaction rates are comparable with the potential sweep rate, voltammograms are affected by both kinetic and thermodynamic characteristics of coupled reactions and it is just under these intermediate conditions that kinetic investigations by LSV and CV are particularly profitable.

**Table 1** Trend of the parameters characterizing linear sweep and cyclic voltammetric responses for uncomplicated reduction processes

Parameter	Process		
	Reversible	Totally irreversible	Quasireversible
$i_p/\nu^{1/2}$	Independent of $\nu$ ; $i_p/\nu^{1/2} = 2.688 \times 108n^{3/2}AD_0^{1/2}C_0^b$ at 25°C	Independent of $\nu$ ; $i_p/\nu^{1/2} = 2.987 \times 108\alpha^{1/2}n^{3/2}AD_0^{1/2}C_0^b$ at 25°C	Slightly dependent on $\nu$ ; it changes from 1.00 to $1.11\alpha^{1/2}$ for about a 108-fold increase in $\nu$
$i_{\text{pb}}/i_{\text{pf}}$	Unity and independent of $\nu$	Lower than one; no relation with $\nu$ has been reported	Unity only for $\alpha = 0.5$
$E_p$	Independent of $\nu$	Dependent on $\nu$ ; it shifts cathodically by $1.15RT/\alpha nF$ mV for a 10-fold increase in $\nu$ (29.5/ $\alpha n$ mV at 25°C)	Dependent on $\nu$ ; for a 10-fold increase in $\nu$ the cathodic shift is smaller than $1.15RT/\alpha nF$ mV
$E_p - E_{p/2}$	Independent of $\nu$ and equal to: $-2.199RT/nF$ mV ( $-56.5/n$ mV at 25°C)	Independent of $\nu$ and equal to: $-1.857RT/\alpha nF$ mV ( $-47.7/\alpha n$ mV at 25°C)	Slightly dependent on $\nu$ ; it changes from $-2.199RT/nF$ mV to $-1.857 \times RT/\alpha nF$ mV (from $-56.5/n$ to $47.7/\alpha n$ mV at 25°C) for about a 108-fold increase in $\nu$
$E_{\text{pb}} - E_{\text{pf}}$	Independent of $\nu$ and equal to: $2.218RT/nF$ mV (57.0/ $n$ mV at 25°C)	Dependent on $\nu$ according to: $\Delta E_p = \{RT/[\alpha(1-\alpha)nF]\}[0.780 - \ln k_{\text{sh}} + \ln(D_0a)^{1/2}] + (RT/nF)[\ln(1-\alpha)^{1/2(1-\alpha)} + \ln \alpha^{(1/2\alpha)}]$	Dependent on $\nu$
$i$ at the foot of the peak	It depends linearly on $\nu^{1/2}$	Independent of $\nu$	It depends on $\nu^{1/2}$ in a nonlinear way

$i$ : current,  $\Delta E_p$ : peak potential separation =  $E_{\text{pb}} - E_{\text{pf}}$  (V).

By way of illustration of the use of LSV and CV to characterize chemical reactions coupled with an electron transfer, the electrochemical pathway relative to electrocatalytic processes (eqn [7]) will be briefly considered. It involves the homogeneous reaction of the reduced product R of a reversible charge transfer with a nonelectroactive substrate Z, allowing regeneration of the electroactive species O, and the concomitant formation of a nonelectroactive product P:

The condition  $(C_Z)^b \gg (C_O)^b$  is usually adopted because it makes relevant responses easier to be interpreted, thanks to the attainment of pseudo-first-order conditions allowing a pseudo-first-order rate constant  $k'_f = k_f(C_Z)^b$  to be adopted.  $(C_Z)^b$  is the bulk concentration of a nonelectroactive analyte ( $\text{mol cm}^{-3}$ ).

To account for the effect of the homogeneous regeneration reaction on the relevant voltammetric profiles, it is convenient to compare this rate constant with the mentioned normalized potential scan rate by adopting the dimensionless kinetic parameter  $k'_f/a$ . Two limiting cases can be recognized. In the former, encountered at scan rates so high as to make  $k'_f/a$  very low, the chemical reaction cannot occur significantly in the timescale of the experiment, thus leading to responses typical for uncomplicated reversible charge transfers. At the other limit, for  $\nu$  so slow as to make high  $k'_f/a$ , the regeneration reaction is allowed to occur quantitatively during the potential sweep and the response is no longer peak-shaped but assumes a sigmoidal shape, as shown in Figure 4. This is because a steady-state for the electroactive species is attained by mutual compensation of its subtraction by the electrode reaction with its chemical regeneration. Under these kinetic conditions, the plateau current attains the following limiting value for high enough overvoltages:

$$i_{\text{lim}} = nFA(C_O)^b(D_O)^{1/2}(k'_f)^{1/2} \quad [8]$$

Such a current, independent of  $\nu$ , enables the homogeneous kinetic constant to be evaluated. To avoid being compelled to know all the experimental quantities accompanying  $k'_f$  in eqn [8], it is convenient to introduce its ratio with the corresponding diffusion controlled current (see eqn [5]), which can be recorded either in the absence of the substrate Z or at scan rates high enough to cancel the effect of the chemical step.

**Figure 4** Theoretical LSV curves for electrocatalytic processes involving reversible charge transfers under pseudo-first-order conditions. Kinetic parameter  $= k'_f/a$ ; potential scale is  $n(E - E_{1/2})$ .

As to CV responses, they display the backward peak typical of uncomplicated reversible processes in the mentioned first limiting case ( $k'_f/a \rightarrow 0$ ), while no backward peak is found for high values of  $k'_f/a$ . Once again, intermediate situations are encountered for intermediate values of  $k'_f/a$ .

By using similar arguments it is possible to anticipate and expound the responses for any type of electrochemical process involving coupled chemical reactions, which are usually classified by using letters indicating the nature of the steps involved. Accordingly, E indicates an electron transfer step and C indicates a chemical step. Thus, a sequence in which a chemical reaction follows a charge transfer is named EC process, while sequences involving a chemical reaction preceding the electron transfer or interposed between two subsequent electrode steps are named CE and ECE processes, respectively. The characteristics displayed by the responses relevant to these types of usual processes are reported in Tables 2–4 summarizing the criteria adopted for characterizing the process involved and for evaluating the relevant kinetic quantities.

### Adsorption Processes

In some electrochemical processes, reactants, intermediates, or products can be either confined onto the electrode surface (adsorbed species, oxide layers,

covalently attached species, redox polymer films) or even the electrode material itself, as in electrodeposition and electrodisolution. These surface phenomena cause different effects on voltammetric responses, depending on their characteristics (adsorption isotherm, adsorption kinetics, electron transfer coupled to adsorption, etc.), so that a generalized treatment is rather problematic. Consequently, only a brief survey is provided here, aimed at recognizing the presence of surface processes.

The interaction degree with the electrode surface allows a rough distinction to be made, in that weakly adsorbed species cause only enhancement of peak currents. In particular, LSV and CV forward peaks higher than those expected for uncomplicated charge transfers (eqn [5]) are found when the weakly adsorbed species is the reactant, while only enhancement of CV backward peaks is recorded for weak adsorption of the electrode product.

On the contrary, a separate adsorption peak is displayed prior to or after the diffusion-controlled peak when redox products or reactants, respectively, are strongly adsorbed. These adsorption-controlled peaks can be identified because they are symmetrical about  $i_p$ , unlike diffusion-controlled peaks, and a linear dependence of their height with  $(C_0)^b$  is usually observed only in a narrow range of low concentrations, while a constant value for  $i_p$  is attained at higher  $(C_0)^b$ . Moreover,  $i_p$  for adsorption peaks increases linearly with  $v$  instead of  $v^{1/2}$  (eqn [5]), because the electrode-solution interphase, in the presence of adsorbed species, behaves like a capacitor, whose capacitive current ( $i_c$ ) is

$$i_c = dq/dt = C_{dl}(dE/dt) = C_{dl}v \quad [9]$$

where  $C_{dl}$  is the double layer differential capacity depending on both the electrode material and solution composition, as well as on the electrode potential and the analyte concentration, although moderately.

Comparison of eqn [9] with eqn [5] points out that capacitive currents are usually negligible with respect to Faradaic currents at high enough analyte concentrations, but they prevail at very high  $v$ .

## LSV and CV at Microelectrodes

The latest development in LSV and CV has been achieved by the introduction of microelectrodes that are metal or carbon electrodes with diameters usually in the range 0.1–100  $\mu\text{m}$ . Microelectrodes with dimensions down to 0.1  $\mu\text{m}$  are, however, produced by specialists in small numbers worldwide. They were originally developed for *in vivo* biological and

	$k_f/a < 1$ ( $k_b/a \ll 1$ )	Uncomplicated one-electron reversible process $[\pi^{1/2}\chi(at)] = 0.4463$ ; $(E_{p/2} - E_p)n = 56.5 \text{ mV at } 25^\circ\text{C}$ ; $\delta E_{p/2}/\delta \log v = 0$ ; $i_{pb}/i_{pf} = 1$ ; $E_p = E_1^0 - 29/n \text{ mV at } 25^\circ\text{C}$	

medical measurements and attracted initially little attention in the belief that not only the relevant low currents present measurement problems, but also no significant difference would exist between performance of large and small electrodes. Only more recently did it become clear that a decrease in surface area results in improved performance, due to the expansion of the inherently small diffusion layer in the

timescale of the experiment that is greater than the dimensions of the electrode. Consequently, relatively large diffusion layers develop a few seconds after current starts, so that more electroactive particles reach the electrode per unit time and surface area than in the case of conventional electrodes. This means that despite the currents being lower at micro-electrodes, current densities are higher by several

orders of magnitude compared to those at conventional electrodes, so that the Faradaic to capacitive current ratio is drastically improved, allowing lower detection limits ( $10^{-8}$ – $10^{-9}$  mol l $^{-1}$ ) to be attained. Moreover, microelectrodes enable high-quality voltammograms to be recorded even in poorly conducting media (e.g., gas phases or nonpolar solvents), thanks to their small currents (in the nA and pA range) making negligible the relevant ohmic drop. They are virtually nondestructive of the species analyzed, thus being suitable for refined applications, such as *in vivo* measurements, lithography, and electrochemical scanning tunneling microscopy. Nevertheless, microelectrodes require very effective shielding and instrumentation designed suitably to avoid ripple and noise effects, very critical with small currents, which cannot be eliminated with standard equipments.

When CV is conducted at stationary microelectrodes with slow  $\nu$ , in both forward and backward scans sigmoidal current-voltage curves are found which are usually coincident, except for processes involving coupled chemical reactions that display more or less marked hystereses. This sigmoidal shape (steady-state current) can be accounted for by considering the radial diffusion to the edges of ultramicroelectrode surfaces that is very important at slow  $\nu$ , so as to make the diffusion rate of analyte molecules to the electrode surface comparable with the charge transfer rate.

On the contrary, when fast scan rates are used to record cyclic voltammograms at microelectrodes, the radial diffusion to the edges of electrode surfaces becomes negligible and the majority of the diffusion is perpendicular to the electrode surface (usual planar diffusion), thus leading to peak-shaped responses like at conventional electrodes. However, the little currents flowing at these small electrodes result in a very small ohmic drop and this profitable advantage, accompanied by the very favorable ratio between Faradaic and capacitive current mentioned above, permits the use of extremely high scan rates. Thus, while at conventional electrodes  $\nu$  of hundreds of V s $^{-1}$  cannot be overcome, microelectrodes enable sweep rates up to 10<sup>5</sup> V s $^{-1}$  to be used, allowing shorter timescales to be explored and faster reactions to be studied.

## Analytical Applications

Analytical applications of LSV and CV include characterization and quantitative determination of electroactive analytes. Characterization is mainly based on the response position on the potential scale, easily estimated by LSV measurements, even though CV

may provide some additional information about the reversibility of the charge transfer and the presence of adsorptions or coupled chemical reactions. Conversely, quantitative determinations are usually performed solely by LSV since they are based on the response height, so that no additional information is provided by CV.

The detection limit (DL) in LSV is mainly governed by the ratio of the Faradaic signal to charging current background. By restricting our considerations to uncomplicated charge transfers, Faradaic currents are  $i_f = kC\nu^{1/2}$  (eqn [5]), while charging currents are  $i_c = k'\nu$  (eqn [8]), where  $k$  and  $k'$  are constants. Their ratio,  $i_f/i_c = k''C\nu^{-1/2}$ , where  $k'' = k/k'$ , points out that the less favorable DL is achieved at fast  $\nu$  and low concentrations. Typical scan rates used for analytical purposes are in the range 10–1000 mV s $^{-1}$  and offer acceptable compromise for achieving close to optimum performance. Under such conditions, approximately an order of magnitude improvement in DL is gained over conventional d.c. voltammetry, so that concentrations as low as 10 $^{-6}$  mol l $^{-1}$  can be determined by LSV in aqueous media.

More complicated considerations must be adopted for analytes undergoing adsorption processes. In most of these cases capacitive currents lead, however, to profitable determinations characterized by lower DL (even 10 $^{-8}$  mol l $^{-1}$ ).

Despite the dependence of  $i_p$  on charge-transfer kinetics (eqns [5] and [6]), the sensitivity of LSV is almost independent of the reversibility degree (only a decrease of ~25% is found on passing from a Nernstian to a totally irreversible process with  $\alpha = 0.5$ ). This fact makes LSV the most sensitive voltammetric technique for analytes involved in irreversible processes because pulsed voltammetric methods or alternating current voltammetry provide for these processes very low signals.

In routine analytical work, the main advantages of LSV are: (1) increased sensitivity; quickly recorded current-potential curves, (2) specificity due to both a large available timescale and improved resolution of peak-shaped curves. This last advantage is, however, rather questionable in some cases because the presence of quite close preceding peaks, as shown in Figure 5, makes difficult the correct baseline to be individuated, even when resorting to the procedures mentioned above (Figure 2).

A recent advanced analytical application of LSV and CV is their introduction in electrochemical detectors for flow analysis (HPLC, EC). Fast-scan LSV and CV (20–1000 V s $^{-1}$ ), performed at the rising portion of the typical peaks afforded by these hydrodynamic methods with microelectrodes suitably positioned at the outlet of the flowing system, provide

**Figure 5** Voltammogram relative to the reduction (or oxidation) of the analyte (2) in the presence of another species (1) more easily reduced (or oxidized) when a little difference exists between  $(E_p)_2$  and  $(E_p)_1$ .

in fact additional resolving power. Thus, for instance, peaks separated incompletely in time can be resolved voltammetrically.

## Introduction

Stripping voltammetry (SV) comprises one of the major families of electroanalytical chemistry. The strength of SV is in its extremely low detection limits ( $10^{-10}$ – $10^{-11}$  mol l $^{-1}$ ). Its remarkable sensitivity is achieved through a preconcentration step in which the target analyte (commonly a metal ion) is accumulated onto working electrodes. This step is followed by the measurement (stripping) step, in which the preconcentrated analyte is stripped back to the solution, a process resulting in a current response

proportional to the analyte concentration in the sample. The different versions of SV depend primarily upon the nature and direction of the preconcentration and measurement steps. Anodic stripping voltammetry (ASV) is the most widely used form of stripping analysis. The extremely low detection of ASV, coupled with its high accuracy, multielement and speciation capabilities, modest cost, and suitability to onsite and online measurements, makes it one of the most powerful techniques for trace metal analysis. This article covers the main aspects of ASV, including past and recent developments of working electrodes, analytical methodologies, instrumentation, and applications in trace metal analysis.

## Principles of ASV

In ASV, the metals are deposited by electrolytic reduction (at a controlled negative potential), and are

**Figure 1** Steps in anodic stripping voltammetry of a metal ion with the reduction–accumulation process at constant potential, and the oxidation of the metal deposited on the electrode.

subsequently being measured during an anodic (positive) potential scan (**Figure 1**)

(S is the substrate electrode). The aggregative state of the concentrate on the electrode may be an amalgam or a solid phase. This depends on either the type of the working electrode employed, or the target element investigated.

ASV can be used for trace measurements of more than 20 elements that can be readily reduced to the metallic state and reoxidized. Most successful are ASV measurements of amalgam-forming elements, such as lead, cadmium, copper, zinc, thallium, bismuth, tin, or antimony, at a mercury working electrode. The amalgam-forming preconcentration step is given by

This illustrates that the deposited metal dissolves in the mercury electrode. Other elements, such as selenium, arsenic, mercury, silver, gold, or tellurium, which either do not form amalgam or oxidize at potentials anodic to that of mercury can be measured by ASV using a variety of solid electrodes. The deposition step is usually carried out under conditions of forced convection to facilitate the transport of the metal ions to the electrode surface. The convective transport is achieved mainly by electrode rotation, solution stirring, and flow. The deposition potential ( $E_d$  in **Figure 1**) should be  $\sim 0.3$ – $0.4$  V more negative than the reduction potential of the metal ion to ensure an efficient deposition process. The duration of the preconcentration step is selected according to the

**Figure 2** Typical stripping voltammogram recorded at an HDME for a mixture containing zinc, cadmium, lead, and copper, each at  $1 \times 10^{-8} \text{ mol l}^{-1}$ .

concentration level of the metal ions in question, from less than 1 min at the  $10^{-7} \text{ mol l}^{-1}$  level to  $\sim 5$ – $10$  min for  $10^{-9}$ – $10^{-10} \text{ mol l}^{-1}$  concentrations. Under such conditions, only a small fraction of the metal is actually being deposited, and therefore ASV is practically nondestructive of the sample investigated. The measurement step is carried out in a quiescent solution, by applying an appropriate potential scan. During the sweep, the amalgamated metals, or metal solid phases, are reoxidized to give rise to anodic peaks. The resultant current–potential stripping voltammogram (**Figure 2**) provides both the qualitative identification (from the peak potential) and the quantitative information (from the peak height, or peak area). The latter measurements are usually performed by using classical calibration procedures. However, under given conditions, calibrationless approaches may also be employed.

Dissolved oxygen, which is electrolytically reduced at the mercury or solid electrodes to yield large background currents, is, in general, removed from the solution by purging high-purity nitrogen through the solution for  $\sim 5$ – $10$  min prior to the preconcentration step. A supporting electrolyte (usually a salt or acid over the concentration range  $0.1$ – $0.5 \text{ mol l}^{-1}$ ) is added to the solution to minimize resistance and migration effects. Numerous voltammetric techniques can be used for the stripping step. Linear sweep voltammetry is an effective means and requires only simple instrumentation. Pulse-voltammetric waveforms such as differential pulse and, particularly square wave, are especially useful for the stripping step as they effectively correct for background current contributions. In addition, square wave voltammetry allows minimizing the interference due to dissolved oxygen, and its use therefore eliminates the need for the time-consuming sample de-aeration.

Like most analytical techniques, ASV is subject to various interferences. The major interferences include the formation of intermetallic compounds (e.g., copper–zinc), overlapping peaks (e.g., tin–lead, copper–bismuth), or surface blockage by surfactants. These can all be minimized or eliminated if adequate attention is given to certain key operations. For instance, using mercury electrodes, the formation of intermetallic compounds can be minimized by: reducing the amount of metals within the electrodes; addition in the sample solution of a third element that forms a more stable intermetallic compound with one component of the binary system (e.g., the copper–zinc problem is circumvented by adding an excess of  $\text{Ga}^{3+}$  ions); selective plating of the metal ions. The overlapping peaks problem, in some cases, can be addressed by using in the sample solution a suitable complexing agent that shifts the stripping peak potentials according to the stability of the complexes formed. Alternatively, the medium exchange procedure can also be employed. The latter involves the deposition of metals from the sample medium, followed by stripping them in a different solution containing a more suitable electrolyte. This approach improves the selectivity in the stripping step and may also minimize interference caused by various sample components. The direct determination of heavy metals in real samples is often complicated by a variety of organic compounds that are present in different forms. Organic matter may adsorb on the electrode surface, giving rise to unpredictable effects on the ASV responses. In general, removal or destruction of the surface-active substances is necessary before the ASV measurements are carried out. This is usually accomplished by ultraviolet irradiation and hydrogen peroxide or ozone oxidation procedures.

In addition to the above considerations, the analysts should be aware that they are working with extremely dilute solutions and should thus give proper attention for the minimization of contamination risks, adsorption losses, and other alteration during the sampling, storage, and measurement. The reagents used for the preparation of the supporting electrolyte and metal standards should be of the highest purity possible.

## ASV Working Electrodes

Since the advent of ASV, a great effort has been made in the development of suitable working electrodes able to widen the number of elements that can be analyzed, improve sensitivity, accuracy, and reproducibility, lower the detection limits, make the measurements as easier and rapid as possible, and minimizes interference from sample matrices.

The most practical electrodes for ASV are the hanging mercury drop electrode (HMDE) (formed at the tip of a glass capillary), especially in its static mercury drop electrode (SMDE) version, and the thin mercury film (TMF) electrode (Figure 3).

The HMDE consists of a small mercury drop with radius usually not exceeding 1 mm, which hangs by thread in a glassy capillary. The SMDE version utilizes a method of drop formation in which the mercury drop is dispensed rapidly by a solenoid-activated valve, and then allowed to hang stationary at the tip capillary. The drop size in this case can vary over three dimensions and are described as small, medium, and large. TMF is prepared by coating a suitable substrate with a film of metallic mercury. HMDE and TMF are somehow complementary. HMDE has the capability of renewing the electrode surface and therefore minimizes memory effects. However, it is bulky and requires a mercury reservoir and regular maintenance of the capillary. Because of its larger area-to-volume ratio, the mercury film electrode offers higher preconcentration efficiency (i.e., higher sensitivity and lower detection limit) and sharper peaks. In TMF, the mercury film is usually plated electrochemically from solutions containing mercury ions by reduction them under convective transport and negative polarization of the substrate. The mercury film can be preplated before the analysis (*ex situ* plating) or prepared *in situ* (by adding, typically,  $10^{-4}$ – $10^{-6}$  mol l $^{-1}$  mercury ions to the sample

**Figure 3** Schematic of: a hanging drop mercury electrode (A) and a thin mercury film electrode (B).

solution). By far the commonest substrate material for mercury film is carbon due to its chemical inertness and broad useful potential range. Glassy carbon, a vitreous form of isotropic carbon, is the most useful support for the mercury film. Noble metals, or films of noble metals on carbon, such as platinum, gold, silver, and iridium, have also been used as substrates. Deposition of mercury on these substrates does not result in a true homogeneous mercury film, since these metals dissolve to a different extent in mercury, forming metal-amalgam electrodes. This may enhance the interaction of the analyte with the metal substrate, causing interference due to the formation of intermetallic compounds and difficulty in the interpretation of peaks. A more recent method of mercury plating relies on the modification of the electrode surface with a mercury compound (e.g.,  $\text{HgO}$  or  $\text{Hg}^{2+}$  incorporated in Nafion) that, as in the *in situ* plating procedure, produces metallic mercury during the deposition step. Although less used, an alternative to electrochemical plating of mercury onto metal substrates is simply to dip amalgamating noble metals electrodes directly in pure mercury.

The substrate for mercury deposition can be either of millimeters (the so-called macroelectrodes), or micrometers in dimension. The microelectrodes resulting in the latter case have gained wide acceptance in ASV in the last two decades, owing to their favorable analytical properties. In particular, the enhanced mass transfer obviates the need for convective transport during the deposition step and for a rest period before stripping, while makes ASV responses less affected by convective forces in flowing systems. The minimal ohmic drop allows measurements to be carried out in low conducting media without deliberate addition of supporting electrolyte. This largely avoids contamination from external chemicals when ultratrace element analysis has to be performed, while existing chemical equilibria in real samples are not altered. Moreover, due to their small dimensions microelectrodes are suited for assays of extremely small sample volumes. Microelectrode arrays of carbon, iridium, platinum, and gold, fabricated by lithographic processes, offer a further advantage over individual microelectrodes, when ASV assays of very low concentration levels of metal ions have to be performed. The very low current associated to a single microelectrode is amplified, even by several orders of magnitude, at a microelectrode array. In this way, instrumental inability of detection of very low currents is overcome. The developments in the technology of screen-printed electrodes have also impacted on ASV measurements. The screen-printing technology offers large-scale mass production of extremely inexpensive and yet highly reproducible

electrode strips. Such strips rely on planar working and reference electrodes on a plastic or silicon substrate, thus making a self-containing, minuscule electrochemical cell, requiring only sample droplets for ASV measurements. Mercury-coated screen-printed electrodes have been developed for use as low-cost disposable metal-sensing devices. Additional improvements have also been achieved by designing screen-printed arrays of microdisks, the radius of each disk a few micrometers.

A major source for ASV interference arises from adsorption of surface-active compounds on the electrode surface and its consequent fouling. The result is an erratic behavior of the electrode. Coating of the mercury film with a permselective polymeric thin film or a membrane may be useful to address surfactant passivation effects. The modified surface allows analyte species to reach the electrode while excluding any interfering species present in the sample. On the other hand, chemical modification of the mercury film may enhance, for instance, by ion exchange, the selectivity and sensitivity of the ASV analysis toward the analyte of interest. A variety of protective coatings have been employed that range from simple cellulose acetate and Nafion membranes to more complicated polymers. Very attractive electrode systems, which allow ASV measurements of trace metals in real samples, are based on agarose-gel-covered mercury-coated iridium microelectrodes and the corresponding array version. In these cases a mercury microelectrode (or an array) is covered with a gel layer much thicker than the electrode radius, but thin enough to allow quick equilibration with the sample solution. The gel membrane prevents the microelectrode from being fouled by colloids and biopolymers, usually encountered in real samples, and protects the electrode from variable hydrodynamic occurring in the sample investigated. An advance of the array version allows addressing each electrode individually, so that quasi-simultaneous ASV measurements over all the microelectrodes can be performed. This is very useful for real-time, high-spatial resolution concentration profile measurements at interfaces.

In recent years, there has been a growing concern about the use of pure mercury as an electrode material in ASV measurements, owing to its toxicity. Intensive research efforts have been devoted to the development of alternative stripping electrodes, with performance approaching that based on mercury ones. To this purpose different bare solid electrodes of carbon, gold, platinum, silver, and iridium, either of conventional or microscopic dimensions (including microelectrode arrays), have been used directly as substrates for the detection of trace levels of heavy metals, such as copper, lead, cadmium, and zinc.

These mercury-free electrodes, under particular conditions, provide reliable quantification of trace elements. However, multielement analysis is usually complicated by intermetallic interference, multiple ASV peaks, large background contribution due to the relatively low cathodic potential limit (caused by reduction of hydrogen ions, or water).

Bismuth film electrodes (BFEs) have also been introduced as a potentially interesting alternative to TMF. BFE consists of a thin metallic bismuth (rather than mercury) film on substrate materials. Also in this case metallic bismuth is electrodeposited from solutions containing bismuth ions and the substrate of choice is carbon or carbon fibers. Although the bismuth film can be prepared by either *ex situ* or *in situ* procedure, the latter provide better results in terms of reproducibility and detection limits (e.g.,  $2 \times 10^{-9} \text{ mol l}^{-1}$  lead has been detected following 10-min deposition). Although the toxicity of bismuth, as compared to that of mercury, is negligible, which makes these electrodes attractive for routine applications in environmental trace metals analysis, the rather negative oxidation potential of metallic bismuth (less negative of mercury in the absence of strong ligands) poses serious limitations in the anodic range.

Alternative electrode materials, which also address the environmental concerns related to the use and disposal of either liquid mercury or dilute amalgams, are solid metal amalgams such as silver and dental amalgams. These materials are not toxic, cheap, easy to manufacture, and are very stable over a reasonable time (up to several weeks). Dental amalgam electrodes have been found to act similarly to silver electrodes, but with higher hydrogen evolution overvoltage. This makes possible, in addition to other metals like cadmium, lead, copper, thallium, and bismuth, the detection of elements such as zinc, whose reduction step needs to be carried out at very negative potentials. The sensitivity and detection limits of these electrodes compare well with those typical for mercury based electrodes.

In addition to the above types of electrodes, a variety of new and more exotic materials such as boron-doped diamond electrodes, composite electrodes, carbon-film resistors rotograved carbon, with performance comparable with mercury-based electrodes have also been proposed and applied for ASV measurements of trace zinc, cadmium, and lead.

## Anodic Stripping Voltammetry in Flow Systems and Hyphenated Techniques

ASV has been adapted with various flow systems, especially flow injection analysis, sequential injection

analysis, and batch injection analysis. These methods have significant advantages over their batch versions in trace analysis of metal ions, including high sample throughput and simple automated operations, reproducibility, low reagent and sample consumption, less risk of contamination. In addition, operations such as medium exchange or plating of the mercury film online can be accomplished straightforwardly.

To enhance the sensitivity and increase tolerance to surface-active compounds in ASV experiments, different physical phenomena such as ultra- and low-frequency sound, microwave, or controlled heating of the electrode have also been combined with voltammetry. This has provided convenient ASV methodologies for the determination of trace elements in a variety of matrices. The beneficial effects of the physical phenomena rely on the enhanced mass transport during the preconcentration step, and an effective cleaning and activation of the electrode surface (e.g., through cavitation collapse or thermal gradients at the solid-liquid interface) throughout the experiments. By these approaches, ASV of trace lead, copper, and cadmium in highly passivating media have been carried out.

To address problems related to interference due to either organic or inorganic species and to lower detection limits, ASV has also been coupled with other nonelectrochemical analytical techniques. Combination of square-wave ASV and thin-layer chromatography (TLC) has allowed to achieve detection limits down to, respectively,  $5 \times 10^{-11}$ ,  $1.7 \times 10^{-10}$ , and  $7.2 \times 10^{-11} \text{ mol l}^{-1}$  for cadmium, copper, and lead, by performing measurements directly on the TLC plate with minimum pretreatment of the sample. Combination of ASV with atomic spectrometry or inductively coupled plasma-atomic emission spectrometry, inductively coupled plasma-mass spectrometry is capable of analyzing heavy metals present at ultratrace levels (e.g., down to  $1.4 \times 10^{-12} \text{ mol l}^{-1}$  for cadmium and  $1.4 \times 10^{-14} \text{ mol l}^{-1}$  for thallium, following 340 s preconcentration time). These hyphenated techniques represent effective strategies for online operation and convenient medium exchange procedures to eliminate matrix interferences.

## Equipment for ASV Measurements

The equipment requirements for ASV are simple, relatively inexpensive, and commercially available. A typical apparatus includes a three-electrode (or a two electrode, in conjunction with microelectrodes) cell, the voltammetric analyzer, and an X-Y recorder. Reliable and versatile (computerized) instruments,

utilizing various modulation waveforms, are nowadays available from different sources. They are associated with powerful software that allows either generating the various voltammetric waveforms or data acquisition and treatments.

The portable nature and low power demands of electrochemical analyzers satisfy many requirements for onsite and *in situ* measurements. Therefore, a variety of field-based heavy metal analyzers has been developed. They combine advances in sensor technology and hand-held battery powered electrochemical analyzers. Submersible package systems that include several functions such as sampling and mixing the sample with reagents (lab-on-cable) have also been developed for *in situ* natural water analysis. Current efforts focus on the development of miniaturized stripping analytical systems produced by micromachining technology that allows the fabrication of complete laboratory systems on a chip platform (lab-on-chip).

## Applications

The remarkable sensitivity, high accuracy, versatility, and low cost of ASV have led to its application in a large number of analytical problems. The technique has been widely used for the measurements of trace metals in natural waters (including coastal and open ocean or inland waters). The absence of interference from alkali metals makes the technique extremely powerful for analysis of seawaters. Actually, the excess salt fulfills the function of the supporting electrolyte. ASV is especially suited for the study of chemical speciation of metal ions (i.e., determination of different physical-chemical forms of the element), and for their continuous *in situ* monitoring (including ship-board operations). By coupling microelectrode (or microelectrode arrays) with rapid square-wave voltammetry heavy metal ions can be determined at different levels in the water column or at the sediment water interface. Moreover, reliable measurements of trace metals can also be performed directly in low ionic strength aquatic systems such as river and lake waters, rain, and snow. Measurements of complexation capacity, oxidation states, or stability constants represent typical stripping speciation experiments. Other environmental applications include analysis of sediments, rocks, soils, fly ash, and airborne particulate matter. Recent applications are concerned with monitoring of the diffusion processes of heavy metal ions at liquid-liquid and solid-liquid interfaces with steep concentration gradients.

ASV is also widely used for trace metal analysis in body fluids (blood, urine, etc.) and tissues, including

highly reliable blood lead measurements. It is highly suitable for many industrial applications, including assays of food and drinks, gasoline, paint, alloys, or plating baths. High sample throughput, desired for metal ions industrial quality control applications, can be achieved by coupling ASV with high-speed flow injection systems. The use of portable, battery-operated instruments, disposable and microelectrodes, and versatile flow-through stripping systems have greatly facilitated decentralized (onsite) applications of ASV in various fields.

### Introduction

Voltammetry is based on the measurement of a current response as a function of the potential applied to a voltammetric cell. Stripping voltammetry (SV) forms a subdivision of voltammetry and constitutes one of the most important groups of techniques in electroanalytical chemistry. The major advantage of SV is its extremely low limits of detection ( $10^{-10}$ – $10^{-12}$  mol l<sup>-1</sup>), which are the result of a preconcentration step in which the analyte is accumulated onto or into the working electrode. In the subsequent stripping step, the preconcentrated analyte is stripped back into the solution, whereby the observed current response is proportional to the analyte concentration in the sample. In addition to the excellent sensitivity of SV, this group of techniques also offers multielement and speciation capabilities, is suitable for automated on-line and *in situ* measurements, and utilizes low-cost instrumentation. Anodic stripping voltammetry (ASV) and cathodic stripping voltammetry (CSV) are the two different versions of SV, and differ in the nature of their preconcentration and stripping steps. In ASV, a cathodic preconcentration step is undertaken which is followed by a potential scan toward more positive potentials and the anodic (oxidative) currents are determined. Whereas in CSV, an anodic preconcentration step is undertaken, which is followed by a potential scan towards more negative potentials and the cathodic (reductive) currents are determined. This article discusses the technique of CSV and its applications in natural water analyses.

### Principles of Cathodic Stripping Voltammetry

Cathodic stripping voltammetry is a widely utilized group of electrochemical techniques for the

quantitation of trace and ultratrace analytes in complex environmental, clinical, and industrial samples. The excellent sensitivity resulting from the preconcentration step allows the determination of analytes in very dilute samples. The electrochemical preconcentration process in CSV may consist of anodic precipitation of an insoluble salt (conventional CSV), or adsorption of an appropriate surface-active complex of a metal (adsorptive CSV). The preconcentration requires little or no added reagent, thereby minimizing the risk of sample contamination. The preconcentration step also improves selectivity and stability of the method by isolating the analyte from the sample matrix. Various voltammetric waveforms can be employed during the stripping step, including linear sweep, differential pulse, square wave, staircase, or alternating current operations.

The basic instrumentation for CSV consists of a potentiostat, a three-electrode cell (working electrode, reference electrode, and counter-electrode), and a computer for automated measurements and data acquisition. Modern potentiostats are simple, low-cost, and able to perform a range of scan forms. The Ag/AgCl/KCl reference electrode is commonly used and the counter-electrode may be a platinum wire or a carbon rod. In CSV, it is normal to employ a stationary working electrode and the most popular electrode is the hanging mercury drop electrode (HMDE). The advantage of an HMDE is its reliability. With the formation of each new drop, a new electrode surface is produced. The drops generated by modern HMDEs are very small (e.g., VA Stand 663 from Metrohm (Switzerland) produces drops with an area of 0.52 mm<sup>2</sup>), and safe storage and recycling of the used Hg will ensure minimal environmental and health risks. The solution (typically 5–10 ml) in the voltammetric cell is gently stirred using a polytetrafluoroethylene rod or flue during the preconcentration step. The stirring aids the transfer of analyte to the HMDE surface and decreases the diffusion layer of the mercury drop. The rate of stirring should be reproducible and controlled.

### Introduction

Voltammetry is based on the measurement of a current response as a function of the potential applied to a voltammetric cell. Stripping voltammetry (SV) forms a subdivision of voltammetry and constitutes one of the most important groups of techniques in electroanalytical chemistry. The major advantage of SV is its extremely low limits of detection ( $10^{-10}$ – $10^{-12}$  mol l<sup>-1</sup>), which are the result of a preconcentration step in which the analyte is accumulated onto or into the working electrode. In the subsequent stripping step, the preconcentrated analyte is stripped back into the solution, whereby the observed current response is proportional to the analyte concentration in the sample. In addition to the excellent sensitivity of SV, this group of techniques also offers multielement and speciation capabilities, is suitable for automated on-line and *in situ* measurements, and utilizes low-cost instrumentation. Anodic stripping voltammetry (ASV) and cathodic stripping voltammetry (CSV) are the two different versions of SV, and differ in the nature of their preconcentration and stripping steps. In ASV, a cathodic preconcentration step is undertaken which is followed by a potential scan toward more positive potentials and the anodic (oxidative) currents are determined. Whereas in CSV, an anodic preconcentration step is undertaken, which is followed by a potential scan towards more negative potentials and the cathodic (reductive) currents are determined. This article discusses the technique of CSV and its applications in natural water analyses.

### Principles of Cathodic Stripping Voltammetry

Cathodic stripping voltammetry is a widely utilized group of electrochemical techniques for the

quantitation of trace and ultratrace analytes in complex environmental, clinical, and industrial samples. The excellent sensitivity resulting from the preconcentration step allows the determination of analytes in very dilute samples. The electrochemical preconcentration process in CSV may consist of anodic precipitation of an insoluble salt (conventional CSV), or adsorption of an appropriate surface-active complex of a metal (adsorptive CSV). The preconcentration requires little or no added reagent, thereby minimizing the risk of sample contamination. The preconcentration step also improves selectivity and stability of the method by isolating the analyte from the sample matrix. Various voltammetric waveforms can be employed during the stripping step, including linear sweep, differential pulse, square wave, staircase, or alternating current operations.

The basic instrumentation for CSV consists of a potentiostat, a three-electrode cell (working electrode, reference electrode, and counter-electrode), and a computer for automated measurements and data acquisition. Modern potentiostats are simple, low-cost, and able to perform a range of scan forms. The Ag/AgCl/KCl reference electrode is commonly used and the counter-electrode may be a platinum wire or a carbon rod. In CSV, it is normal to employ a stationary working electrode and the most popular electrode is the hanging mercury drop electrode (HMDE). The advantage of an HMDE is its reliability. With the formation of each new drop, a new electrode surface is produced. The drops generated by modern HMDEs are very small (e.g., VA Stand 663 from Metrohm (Switzerland) produces drops with an area of 0.52 mm<sup>2</sup>), and safe storage and recycling of the used Hg will ensure minimal environmental and health risks. The solution (typically 5–10 ml) in the voltammetric cell is gently stirred using a polytetrafluoroethylene rod or flue during the preconcentration step. The stirring aids the transfer of analyte to the HMDE surface and decreases the diffusion layer of the mercury drop. The rate of stirring should be reproducible and controlled.

## Conventional Cathodic Stripping Voltammetry

The conventional type of CSV has been used to determine a variety of inorganic and organic compounds that form an insoluble film on the electrode material during the preconcentration step. The most commonly used working electrode is the HMDE. The preconcentration step involves the application of a positive (anodic) deposition potential to the working electrode, with the formation of a sparingly soluble compound with the mercury electrode. The application of the positive potential results in the oxidation of metallic mercury to mercury(I):

and these mercury(I) ions immediately form insoluble salts with, for example, a halide ion ( $\text{X}^-$ ) on the surface of the electrode, following the reaction:

After the preconcentration step, the deposit is stripped from the electrode by application of a scan toward more negative (cathodic) potentials. In the potential scan, the mercury salt is reduced to metallic Hg and  $\text{X}^-$ :

CSV has proved suitable for the determination of halides (iodide, bromide, chloride) and sulfides, and a number of organic compounds, including biological molecules (cystine, glutathione), drugs (penicillin), and pesticides (see Table 1). The organic compounds typically contain sulfur, with the consequent formation of an insoluble mercury salt during the anodic deposition step. The reduction potential of the various compounds determined by CSV is shifted toward more cathodic potentials relative to the uncomplexed mercury(I). The extent of the shift depends on the strength of the formed compound or complex.

An example of the determination of iodide in an aqueous sample using CSV is presented in Figure 1.

The preconcentration potential used was  $-0.05\text{ V}$  applied for 60 s, with the appearance of the reduction peak at a potential of  $-0.41\text{ V}$ .

Although the HMDE is the most commonly used working electrode for CSV, the applications of other types of electrode materials have been reported. For example, silver electrodes have been used for the CSV determination of halides and sulfides. In addition, the use of carbon and platinum electrodes has been reported for metal cation determinations, including iron(II), cerium(III), manganese(II), thallium(I), and lead(II). Such CSV measurements involve the precipitation of insoluble metal hydroxides on the electrode surface during the precipitation step. The drawback of the use of solid electrode materials is the poor reproducibility of the analysis and the low sensitivity, as a result of irregularities on the electrode surface and irreversible reduction of hydroxides (in the case of metals).

CSV can be seen as 'the mirror image' of ASV, but important differences can be noted between the two techniques. In ASV, the deposited metal dissolves in the mercury and forms an amalgam. In CSV, the insoluble salt deposits on the surface of the electrode and a film is formed. For this reason, the optimal electrode geometries for the techniques are different. In ASV, the maximum peak currents are achieved when the electrode volume is as low as possible (i.e., when using a mercury film electrode), because the current intensity depends on the concentration of the

**Figure 1** Scan of iodide in deionized water. Preconcentration potential  $-0.05\text{ V}$  for 60 s. HEPES (*N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid) was used as pH buffer (pH 7.8,  $10\text{ mmol L}^{-1}$ ) and Triton X-100 ( $20\text{ }\mu\text{L}$  of 0.2% v/v) as sensitivity enhancing surfactant. Iodide concentration was  $2\text{ nmol L}^{-1}$ .

**Table 1** List of compounds that can be determined in water by conventional CSV

Chloride	Bromide	Iodide	Sulfide/sulfur	Sulfate
Thiols	Cyanide	Ferrocyanide	Ferricyanide	Arsenic
Selenium	Tellurium	Molybdate	Tungstate	Vanadate
Thiocyanate	Oxalate	Chromate	Succinate	Disulfides
Flavins	Flavones	Pterins	Porphyrins	Hemoglobin
Thioamides	Cysteine	Cystine	Penicillins	Iron(II)
Cerium(III)	Manganese(II)	Thallium(I)	Lead(II)	

metal collected as a mercury amalgam. In contrast, in CSV the current intensity depends on the amount of insoluble film formed and hence on the electrode area. Because of the formation of a film, calibration curves in CSV typically show a nonlinear behavior at high concentrations as a result of surface saturation. At low concentrations, curves are reproducible, and can be used for analytical purposes. In general, interfacial complications, i.e., surface saturation or interferences between analytes, and other experimental difficulties have limited the use of the CSV technique. In addition, uncertainties exist with respect to the selectivity of the CSV methods for the analyses of organic compounds.

## Adsorptive Cathodic Stripping Voltammetry

Adsorptive cathodic stripping voltammetry (ACSV) is a very sensitive technique for the analysis of numerous trace metals ( $\sim 40$ ), which cannot be determined using conventional electrolytic stripping procedures (i.e., ASV). ACSV makes use of a specific added ligand (AL), which is added to the water sample and forms an adsorptive complex with the trace metal(s) under investigation (reaction [IV]):

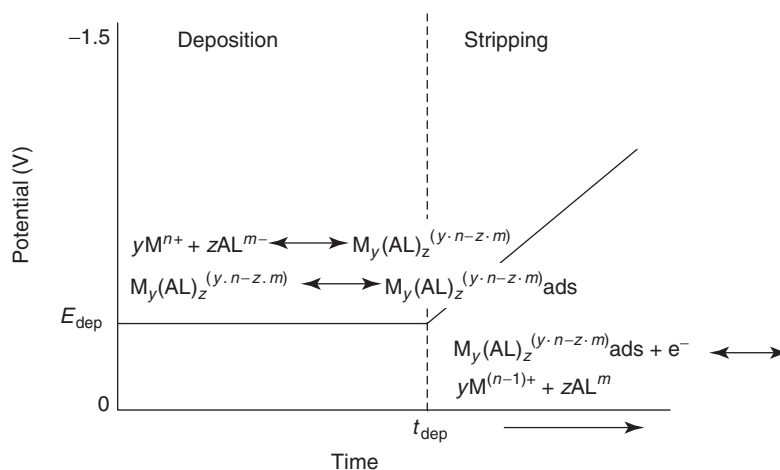

A pH buffer is used to control the pH of the sample, as the formation of the metal–AL complex is pH dependent. Indeed, many of the experimental

conditions used for the ACSV determinations of trace metals are optimized empirically, including pH, deposition potential and time, AL concentration, and waveform. Generally, ACSV is carried out using an HMDE. A minute fraction of the metal–ligand complex is adsorbed on the surface of the Hg drop (reaction [V]) and a potential scan is carried out (see Figure 2). The scan direction is toward more negative potentials and the resulting current is measured.

Figure 3 shows an example of the determination of dissolved Cu in seawater with the use of 8-hydroxyquinoline as AL.

The resultant current–potential stripping voltammogram provides (1) quantitative information, that is, the height of the peak is proportional to the metal concentration; and (2) qualitative information, that is, the potential of the peak is an indication for the metal analyzed. Quantification of metal concentrations in samples during voltammetric analysis is commonly undertaken by use of the standard addition method. This is the preferred method as the sensitivity of the stripping voltammetric analysis may vary between samples of different ionic strength and containing different concentrations of surfactants and natural trace metal complexing organic ligands (see ‘Interferences’ section below).

The current produced during the ACSV scan is the result of the reduction of a reducible group on the ligand or of the metal itself in the adsorbed complex (reaction [VI]). The scan forms applied during ACSV include linear sweep, but fast pulse-voltammetric waveforms (e.g., differential pulse and square wave) are also used if the reduction of the metal–AL complex is electrochemically reversible. The advantages of fast scan forms include compensation against the capacitance current contribution, a reduction of interferences from dissolved oxygen, and an improved

**Figure 2** Steps in ACSV measurements of a metal ion. The procedure involves the formation, deposition, and reduction of the surface active metal–added ligand complex.

**Figure 3** Voltammetric scan of dissolved Cu in seawater. 8-Hydroxyquinoline ( $0.15 \text{ mmol l}^{-1}$ ) was used as the ACSV ligand and HEPES ( $10 \text{ mmol l}^{-1}$ ) as pH buffer (pH 7.8). Voltammetric conditions were: 20 s deposition at  $-1 \text{ V}$ , 8 s equilibration at  $-0.25 \text{ V}$  and 200 Hz square wave scan toward more negative potentials. Scan I is for a seawater sample, and scan II is for the sample plus standard addition ( $5 \text{ nmol l}^{-1}$ , final concentration).

speed of analysis. A detailed schematic of the square wave form is presented in Figure 4.

The optimization of the frequency of the square wave modulation for the determination of Cu using 8-hydroxyquinoline in a low ionic strength solution is presented in Figure 5. This experiment shows that the peak current of the Cu reduction signal increases linearly up to  $\sim 100 \text{ Hz}$ , but decreases gradually at higher frequencies. The linear part of the frequency-signal graph is the result of the efficient reduction of the adsorbed metal-AL complex, which typically occurs as a monolayer on the HMDE surface. At enhanced scan frequencies, the reduction of the metal-AL complex in the monolayer becomes less efficient, and the electron and ion transfer in the low ionic strength medium becomes limiting.

The adsorption step in ACSV is carried out at a carefully controlled potential as it determines the adsorption efficiency. In most cases, an adsorption potential is chosen which is slightly more positive ( $\sim 0.1 \text{ V}$  or more) than the reduction potential of the metal-ligand complex. Figure 6 shows the optimization of the deposition potential for the determination of Zn using ammonium pyrrolidine dithiocarbamate (APDC) as the AL. The optimal deposition potential for this method is  $-0.9 \text{ V}$ , with the reduction

**Figure 4** Detailed schematic of square wave (SW) scan form, indicating the SW frequency and amplitude, potential ( $E$ ) step and sample period.

**Figure 5** Effect of square wave scan speed on reduction peak signal for Cu in low ionic strength solution (deionized water). 8-Hydroxyquinoline ( $0.15 \text{ mmol l}^{-1}$ ) was used as the ACSV ligand, HEPES ( $10 \text{ mmol l}^{-1}$ ) as pH buffer (pH 7.8) and  $10 \text{ nmol l}^{-1}$  added Cu. Voltammetric conditions were: 60 s deposition at  $-0.2 \text{ V}$  and square wave scans toward more negative potentials.

**Figure 6** Effect of deposition potential on reduction peak signal for the determination of Zn using ACSV in deionized water. Conditions:  $0.01 \text{ mmol l}^{-1}$  APDC and  $0.01 \text{ mol l}^{-1}$  borate (pH buffer) with a deposition time of 60 s in the presence of  $10 \text{ nmol l}^{-1}$  added Zn.

potential of Zn appearing at  $-1.05 \text{ V}$  (versus Ag/AgCl/KCl reference electrode).

The accumulation of the metal-AL complex on the surface of the HMDE can be described using the Langmuir adsorption isotherm:

$$\Gamma = \Gamma_m \frac{BC}{1 + BC} \quad [1]$$

where  $\Gamma_m$  is the metal–AL surface concentration corresponding to the monolayer cover and  $B$  the adsorption coefficient. Consequently, plots of deposition time versus peak signal typically show a deviation from linearity at long deposition times as a result of surface coverage saturation. This is illustrated in Figure 7 for a deposition time experiment involving Co (with nioxime as AL and  $\text{NO}_2^-$  as catalyst), which shows a deviation from linearity at times  $>240$  s.

The adsorptive accumulation approach results in a very effective preconcentration with short adsorption times, allowing fast and extremely sensitive trace metal measurements. The limit of detection of ACSV for trace metals is typically on the order of  $10^{-9}$ – $10^{-11}$  mol l $^{-1}$ . Even lower metal

**Figure 7** Effect of deposition time on reduction peak signal for the determination of Co using ACSV in deionized water. Conditions:  $0.01 \text{ mol l}^{-1}$  nioxime and  $0.01 \text{ mol l}^{-1}$  borate (pH buffer) with a deposition time of 60 s in the presence of  $0.5 \text{ mol l}^{-1}$   $\text{NaNO}_2$  and  $1 \text{ nmol l}^{-1}$  added Co.

concentrations can be determined by enhancing the reduction current catalytically through adding an oxidant ( $10^{-12} \text{ mol l}^{-1}$ , e.g., Co ( $\text{NO}_2^-$  added), Pt ( $\text{H}^+$  added), and Ti ( $\text{ClO}_3^-$  added)). ACSV methods have been developed and applied during the last 25 years for a wide range of trace metals. As the formation of a metal amalgam is not a prerequisite for ACSV (in contrast to ASV), methods for any trace metal with a reduction potential within the stability limits of hydrogen evolution and mercury oxidation can potentially be developed. Table 2 lists ACSV methods for direct determination of trace metals in natural waters, together with their limit of detection. Table 2 is not intended as a complete list, neither does it cover all elements for which ACSV methods are available, nor does it include all reported ACSV ligands.

Figure 8 shows the chemical structures of a selected number of ACSV ligands. The organic ligands in Table 2 and Figure 8 contain N and O donor groups (e.g., DMG and 8-hydroxyquinoline), in addition to S donors (e.g., APDC). To be suitable for ACSV, ligands are required to have two properties: (1) the ability to form a complex with the element of interest, and (2) electroactivity (i.e., capability to adsorb onto the surface of the HMDE). Many of the ligands shown in Table 2 and Figure 8 have aromatic ring structures. There are however exceptions, like, for example, DMG, which forms a ring structure on chelation with

**Table 2** Trace elements and added ligands used for ACSV analysis in natural waters

Element	Added ACSV ligand	Limit of detection ( $10^{-9} \text{ mol l}^{-1}$ )
<i>Methods using reduction of element</i>

$\text{Ni}^{2+}$ . The adsorption of the ligands is affected by the deposition potential and it therefore appears that the presence of electrostatic and  $\pi$ -electron interactions are significant for the adsorption process.

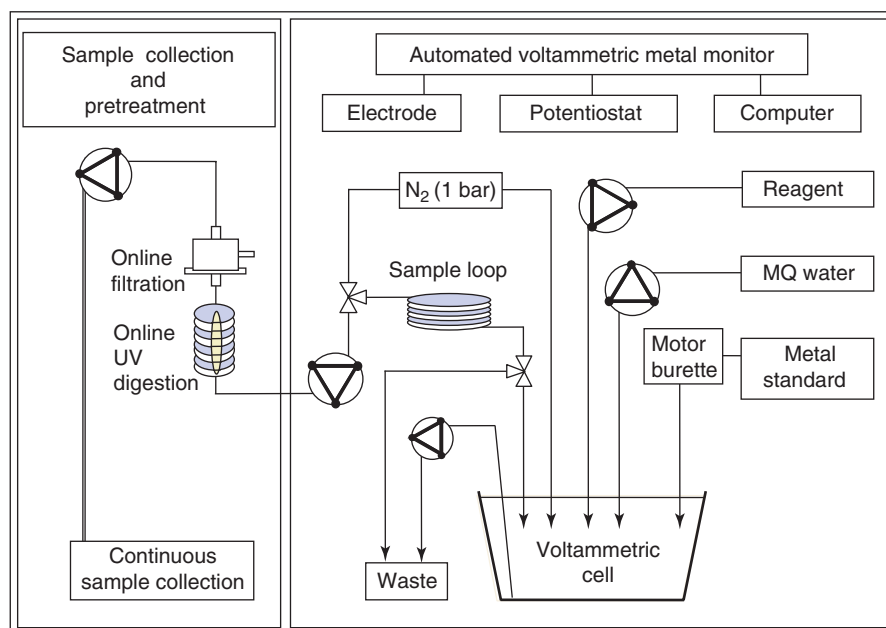

In many cases, ACSV has been utilized as a single-element method. However, a number of ligands allow the simultaneous determination of several elements. For example, catechol allows the determination of Cu, Fe, V, and U in a single measurement, with well-separated reduction peaks. Furthermore, multi-element ACSV methods for HMDE have been developed recently, whereby with the use of a mixture of ACSV ligands up to six trace metals (Cu, Pb, Cd, Ni, Co, and Zn) can be determined simultaneously in coastal and estuarine waters.

### Applications of ACSV

**Shipboard trace metal analyses using ACSV in coastal waters** Trace metal analyses in seawater are challenging because of the low concentrations of the analytes of interest ( $10^{-9}$ – $10^{-12}$  mol l $^{-1}$ ) and the high salt content of the medium. Stripping voltammetric techniques have a major advantage because the analyses can be undertaken directly in seawater, as the preconcentration is performed in the voltammetric cell itself. Alkali metals present in seawater do not interfere with trace metal determinations, but in

many cases actually increase the sensitivity of the voltammetric methods because of their role as electrolytes. The reduction in the sample handling minimizes the risk of sample contamination and allows automation of the instrumentation. Moreover, the portable nature of the instrumentation makes the technique suitable for field deployment. **Figure 9** presents a manifold of a voltammetric system that has been used in the field in an automated batch-mode for trace metal analyses. Aliquots of 10 ml can be analyzed at a rate of one complete measurement every  $\sim 10$ – $20$  min. Each sample is fully calibrated through automated standard additions, resulting in high-quality data required for biogeochemical and pollution studies. A more recent development involves the field deployment of online ACSV systems that use an HMDE in a flow cell arrangement. Such an approach results in very high measurement frequencies with a trace metal analysis every  $\sim 60$ – $90$  s.

The automated voltammetric systems have been used on-board ships for near real-time trace metal measurements of surface seawaters using ACSV. This approach uses underway pumping as a means of sample collection and thereby obviates the need for the vessel to halt for the collection of discrete samples. Sample contamination is prevented by eliminating contact of the seawater with metal components by

**Figure 9** Manifold of an automated voltammetric system for field analysis of trace metals. Sample pickup could be from sample changer, or pumped seawater supply.

**Figure 10** Contour plots of total dissolved Ni in the Gulf of Cadiz, determined on-board ship using automated ACSV with continuous underway sampling during surveys in June 1997 and October 1998 (concentration gradients in  $\text{nmol l}^{-1}$ ). Dissolved Ni was determined using DMG as AL and HEPES as pH buffer.

using inert materials (e.g., Teflon<sup>®</sup>, polyvinyl chloride, polyethylene). Online filtration and ultraviolet digestion is carried out continuously prior to analysis, in order to remove particles and metal complexing organic matter, respectively. **Figure 10** illustrates, with the example of Ni, the advantages of high-resolution monitoring in the coastal waters of the Gulf of Cadiz for surveys in June 1997 and October 1998. The continuous underway sampling and analysis approach resulted in an extensive coverage of the coastal area. Dissolved Ni concentrations were analyzed using a mixed reagent of AL (DMG) and pH buffer (HEPES, pH 7.8). At a ship's speed of 8 knots, and a rate of four to five measurements per hour, the spatial

resolution between samples during automated online metal analyses was between 3.3 and 4.5 km. The distribution of dissolved Ni in **Figure 10** shows enhanced metal levels in the coastal region near the outflow of estuaries. The decrease in Ni concentrations with increasing distance from the coast is the result of mixing of metal-polluted estuarine water with cleaner Atlantic waters.

**Trace metal speciation studies in natural waters using ACSV** The high sensitivity and selectivity of ACSV makes this technique very suitable for trace metal speciation studies. ACSV has consequently been used for this purpose in river, lake, ground, and sea

waters. Speciation analysis involves the determination of different physicochemical forms of trace metals. Metal speciation studies have become important because of the recognition that total dissolved metal concentrations do not yield sufficient information about the toxicity, bioavailability, and geochemical behavior of trace metals in natural waters.

Only a few analytical techniques (including SV and chemiluminescence) are sensitive enough to determine labile/free aqueous metal fractions in natural waters. A great number of trace metal speciation studies have been reported for natural waters utilizing ACSV during the last decade. ACSV has been used to investigate (I) redox speciation, and (II) concentration of naturally present metal complexing organic ligands.

(I) ACSV has been used to determine the different redox species of As, Fe, and Cr in natural waters. In the case of Cr, the thermodynamically stable form of Cr in oxygenated seawater is Cr(VI) (as  $\text{CrO}_4^{2-}$ ). However, significant amounts of Cr(III) have been found in natural oxygenated waters. **Figure 11** shows depth profiles of dissolved Cr species in the Mediterranean Sea. Total dissolved Cr concentrations ranged between  $3\text{--}5\text{ nmol l}^{-1}$ , with somewhat lower Cr(VI) concentrations. Dissolved Cr(III) concentrations (determined as the difference between total dissolved Cr and Cr(VI)) ranged between  $0.2$  and  $1\text{ nmol l}^{-1}$ , with maximum concentrations in the surface layer. Photochemical and biochemical reduction of Cr(VI) have been hypothesized to be responsible for the production of Cr(III) in seawater.

(II) Metal titrations are used to determine the concentration of natural metal-complexing ligands (L) and their conditional stability constants ( $K'_{\text{ML}}$ ), utilizing a ligand competition approach. For this purpose, a seawater sample is divided into typically 10 subsamples, to which increasing amounts of metal are added. After addition of the ACSV ligand and a pH buffer, an equilibration period (typically 12 h) is applied during which the naturally present ligands compete with the added ACSV ligand in a controlled manner. Subsequently, the metal concentrations are measured in the subsamples. Linear or nonlinear data transformation allows the determination of L and  $K'_{\text{ML}}$ , in addition to the free aqueous metal concentration. The natural ligand concentration (L) and  $K'_{\text{ML}}$  provide information about the capacity of natural waters to buffer additional inputs of metals, and the binding strength of L for the metal under investigation, respectively. The free aqueous metal concentration, which is calculated from L and  $K'_{\text{ML}}$ , provides information about the possible biological effects of the metal.

**Figure 12** shows a depth profile of concentrations of natural Cu complexing ligands in the Atlantic Ocean

**Figure 11** Depth profiles of total dissolved Cr, Cr(VI), and Cr(III) in the Mediterranean Sea near Gibraltar ( $37.1^\circ\text{N}$ ,  $5.22^\circ\text{W}$ ), analyzed on-board ship using ACSV with DTPA as AL,  $\text{NO}_3^-$  as catalyst, and acetate as pH buffer.

determined using automated ACSV on-board ship. The depth profile of natural Cu complexing ligands showed a close similarity with *in situ* determined fluorescence, which is a measurement of the chlorophyll concentrations. The maximum ligand concentration coincided with a maximum in fluorescence, indicating that the ligands observed in the Atlantic were derived from phytoplankton. The conditional stability constants of the Cu complexing natural ligands ranged between 12 and 13 (log values) and the calculated free cupric ion concentrations  $[\text{Cu}^{2+}]$  ranged between  $7 \times 10^{-14}$  and  $3 \times 10^{-13}\text{ mol l}^{-1}$ .

### Interferences in ACSV

Dissolved oxygen occurs at high concentrations in natural waters ( $\sim 3 \times 10^{-4}\text{ mol l}^{-1}$ ) and interferes with voltammetric measurements. Therefore, oxygen interference is usually removed by deoxygenation of the sample for a period of 3–5 min using an inert gas

**Figure 12** Depth profile of the concentration of natural Cu complexing ligands (analyses on-board ship) and fluorescence in the Northeast Atlantic Ocean (48° N, 20° W).

like N<sub>2</sub>. Furthermore, many CSV methods are affected by the presence of dissolved organic matter in the samples. The organic compounds can interfere with the analyses because of their surface-active properties, and hence adsorb onto the HMDE and block the adsorption of metal-AL complexes. In addition, organic compounds may complex trace metals and out-compete the AL for the analyte of interest. UV digestion is commonly used to remove the surfactants and metal-complexing organic ligands from the sample. Both UV digestion in a batch and

on-line mode have been reported, and the lamps used are usually medium pressure Hg vapor lamps (between 50 and 1000 W). The ultraviolet digestion is to be undertaken in acidified samples, and typically H<sub>2</sub>O<sub>2</sub> is added as an oxidant to improve organic matter breakdown.

## Introduction

The analytical application of voltammetry to the determination of inorganic compounds is often achieved by the use of three common voltammetric

techniques: anodic stripping voltammetry (ASV), cathodic stripping voltammetry (CSV), and adsorptive stripping voltammetry (AdSV). The basic principles and applications of ASV and CSV have been described elsewhere. Therefore, the focus of this section is on AdSV, which has gained the most interest of all the voltammetric techniques for the determination of inorganic compounds in the past two to three decades.

This technique is remarkably sensitive and, in particular, permits the determination of trace and ultratrace concentrations of numerous substances, many of which cannot be determined by ASV because of their poor solubility in mercury or by CSV because of their inability to form insoluble film with the electrode material. The principles and application of AdSV for the determination of inorganic compounds in various sample materials are described below.

## Adsorptive Stripping Voltammetry

### Background

The merits in the deliberate adsorption of species onto suitable electrode for analytical voltammetric measurement were first evident from Komarek's (a Czech Chemist) work in 1947 when he found that the adsorption of nickel as nickel dimethylglyoximate resulted in substantial enhancement of its polarographic response. The concept was extended by a number of workers in the early 1980s to enable the AdSV determination of nickel and cobalt (as metal dimethylglyoximates) in the picogram to nanogram range with increased sensitivity, improved selectivity, high specificity, and better limits of detection, compared with ASV and CSV.

A major difference between AdSV and other stripping voltammetric techniques is the utilization of a spontaneous adsorption process during the preconcentration step. This involves the preconcentration of the inorganic substance, as a complex, by interfacial accumulation at an open circuit. The adsorbed complex cannot be deposited by electrolysis and significantly larger voltammetric responses are obtained for adsorbed species than for solution-species alone. This has resulted in a substantial improvement in the limits of detection for many inorganic substances by several orders of magnitude compared with the corresponding solution-phase voltammetric measurements, based on the use of ASV and CSV. This substantial improvement in sensitivity, particularly for metals, is due to the formation of metal complex(es) that possess surface-active properties and that can be subsequently reduced during the stripping step with the application of a potential scan. This is particularly beneficial for enhancement of the electrode processes of inorganic substances with extreme irreversible behavior, such as nickel and cobalt. The sensitization factor of this approach is  $\sim 100$ – $1000$  or more, resulting in improved limits of detection for the analytes. AdSV has been successfully applied to the determination of many inorganic substances in various samples, such as biological tissues, blood, foodstuffs, geological materials, groundwater,

industrial plant electrolyte, plant materials, seawater and other natural waters, sediment, sewage, soil, and urine.

### Principles

The measurement of inorganic substances by AdSV involves three main steps, which are similar to those employed in ASV and CSV, but it is distinctly different in its preconcentration step, which does not involve electrolysis. The specific steps in AdSV are:

- (a) Interfacial accumulation, which involves the addition of a complexing or chelating agent to enable the formation of an adsorbable metal complex or chelate at an optimum pH:

This is followed by preconcentration of the metal complex or chelate by adsorption, as follows:

- (b) Equilibration period, which is a brief rest period (usually 15–30 s) when the stirrer is turned off prior to the measurement and it is the same as employed for ASV and CSV.
- (c) Reductive stripping, which involves an application of a negative potential sweep to enable the reduction of the adsorbed metal complex or chelate, as follows:

It is important to note here that the selectivity achieved in AdSV is governed by four important chemical and electrochemical factors: (1) choice of complexing or chelating agent, (2) solution composition, (3) choice of accumulation or adsorption potential, and (4) the required reduction potential for the adsorbed complex. In practice, steps (a) and (b) described above are carried out by buffering a solution that contained the inorganic analyte(s) to an optimum pH, adding a suitable selective complexing or chelating agent, and then preconcentrating a small fraction of the dissolved complex by adsorption onto the electrode (usually a mercury electrode). A carefully controlled potential is usually employed for the adsorption step to ensure optimum adsorption of the dissolved complex. The final step (c) is intended to remove the adsorbed complex by application of a negative potential scan, which may be either a linear DC potential sweep or a potential sweep with superimposed modulations. During the potential scan, the resulting reduction current is monitored simultaneously until the reduction peak(s) for the analyte(s) is evident. The resulting peak current or peak height is directly proportional to the analyte concentration. **Figure 1** shows the responses obtained

**Figure 1** DPAdSV determination of nickel and cobalt in non-acidified swamp water with an MFE. Standard additions: (A) sample only, (B) + 100, (C) + 300 m, and (D) + 500 ng l<sup>-1</sup>.

for simultaneous determination of nickel and cobalt in a water sample by DPAdSV with a mercury film electrode and quantification is achieved by standard additions method. Evidently, the peak current for each metal increased with increasing concentration and this relationship was used to quantify the concentration of each metal in the water sample.

It is widely accepted that the measured reduction peak current in AdSV results from the reduction of either a reducible group on the complex or of the inorganic substance (e.g., a metal in a metal complex) itself in the adsorbed complex. In either case, a necessary requirement in this measurement is that the reducible component must be close to the electrode surface and, as the adsorbed complex usually occurs as a single molecular layer on the electrode, this ensures that the reduction step is efficient. In effect, all or most adsorbed complex is reduced during the negative potential scan. Another important advantage of AdSV is that any oxidation state with a reduction potential within the stability limits of mercury and hydrogen can be used. This has resulted in the successful utilization of this technique for the determination of over 40 inorganic elements at trace and ultratrace concentrations. **Tables 1–3** list some of the inorganic substances that can be determined by AdSV. A detection limit within 0.01–1 nmol l<sup>-1</sup> is readily accomplished by AdSV due to the high efficiency of the reduction step and of the adsorption of the analyte. Lower detection limits can be accomplished by coupling the very efficient adsorptive accumulation of inorganic complexes on electrode surfaces with a catalytic reaction. This approach will be discussed later in more detail.

#### AdSV Based on Complexing Agent Reduction

Some of the inorganic substances that are difficult to reduce in aqueous media can, in some cases, be

determined indirectly by the reduction of the ligand in the complex. However, unlike the reduction of the inorganic substance, it is sometimes difficult to achieve adequate peak separation of different inorganic substances. The reduction potential is often shifted toward more negative potentials than that of the uncomplexed fraction of the ligand due to the stabilization of the reducible group in the ligand. Consequently, the stability of the complex determines the peak potential of the complex, and its separation from the main ligand peak. So, the separation of the peak potentials of complexes of different inorganic substances with the same complexing agent is only possible if they have different complex stabilities.

**Table 2** lists some of the inorganic substances that have been determined based on the reduction of the ligand in the complex. In general, the achievable sensitivity and detection limit for this approach are usually not as good as those obtained with the direct reduction of the inorganic substances due to competitive co-adsorption of the ligand. Nevertheless, detection limits in the low nanomolar range are often achieved by this approach.

#### Catalytic Adsorptive Stripping Voltammetry

Many complexes of metals that can be adsorbed onto electrode surfaces have also been found to be capable of inducing catalytic reactions with electroinactive oxidizing agents or inducing catalytic hydrogen evolution. Consequently, the addition of an oxidant has been used, in some cases, to achieve significant increase in the sensitivity of AdSV by enabling chemical oxidation of reduction products generated from the electrochemical reduction step. Hence, the resulting voltammetric response obtained for such catalytic adsorption stripping voltammetry (CAdSV) is the product of both the effects of the interfacial accumulation (adsorption) and the catalytic reaction, as expressed for the associated faradaic current ( $iF$ ) as follows:

$$iF = (\text{adsorptive enrichment}) \times (\text{catalytic enhancement})$$

The combination of the enrichment and enhancement effects in CAdSV has been successfully used for reactions involving either a single or a two-electron reduction. As indicated in **Table 3**, the inclusion of oxidants, such as nitrite, nitrate, peroxide, bromate, chlorite, chlorate, and hydrogen ions, in solutions have been shown to result in: (1) considerable amplification of the voltammetric responses obtained with AdSV, (2) a reduction in detection limits, and (3) improved selectivity. This catalytic current generation has been successfully used for the AdSV determination of inorganic substances, such as Co, Cr,

BD =  $\alpha$ -benzildioxime; BO =  $\alpha$ -benzoinooxime; BP = 2,2'-bipyridine; CA = chloranilic acid; DHN = 2,3-dihydroxynaphthalene; DMG = dimethylglyoxime; DMTD = 2,5-dimercapto-1,3,4-thiadiazole; DTPA = diethylenetriaminepentaacetic acid; FD =  $\alpha$ -furildioxime; HNB = *N*-hydroxy-*N*-nitroso benzeneamine; MA = mandelic acid; NO = nioxime; NN = 1-Nitroso-2-naphthol; PAN = 1-(2'-Pyridylazo)-2-naphthol; PC = pyrocatechol; TTHA = triethylenetetraminehexaacetic acid.

Fe, Mo, Pt, Rh, Ti, U, V, and W (Table 3). Some of these systems, such as the AdSV measurement of cobalt with nioxime in presence of nitrite as oxidant (Table 3), have been found to increase the voltammetric response by at least four orders of magnitude. In general, the sensitivity obtained for the AdSV measurement of these inorganic substances in the presence of oxidants (Table 3) are much higher than those obtained without oxidants (Table 1) and has enabled the achievement of detection limits in the subpicomolar range. In addition, the utilization of catalytic systems in AdSV has been found to be useful in widening the analytical concentration range and improving the selectivity of the determination.

The main factors responsible for the improvement of the selectivity of CAdSV are: (1) the increase in the

ratio of the faradaic current of the analyte to the faradaic currents of the other substances present in the solution, and (2) the specificity of the reaction of an ion-catalyst with the chosen oxidant. Consequently, the optimization of the sensitivity and selectivity of CAdSV requires careful investigation of the influence of supporting electrolyte composition (choice of complexing agent, oxidant, pH, buffer/electrolyte concentration, etc.) and instrumental parameters (accumulation time, potential, voltammetric mode, scan rate, etc.). In terms of the choice of voltammetric mode, the use of differential pulse (DP) voltammetric mode is most popular because of the high sensitivity and selectivity commonly achieved with this mode. The two other voltammetric modes that are also commonly used with CAdSV are

**Table 2** Some of the complexing agents that have been used for AdSV determination of inorganic substances based on complexing agent reduction

Complexing agent	Inorganic element or compound	Working electrode(s)	pH	Detection limit (nmol l <sup>-1</sup> )
o-Cresolphthalexone	Cerium	HMDE	9.5	2

square wave (SW) and linear sweep (LS) modes (Table 3). The successful use of CAdSV for some speciation studies has also been reported and more interest is expected in this area in the future.

## Important Considerations in AdSV

### Choice of Complexing Agent

As indicated previously, the choice of a suitable complexing or chelating agent is a very important consideration for the successful utilization of AdSV for the determination of inorganic compounds in various sample matrices. It is possible that a chosen complexing agent may be capable of forming complexes with the analyte(s) and many other substances, but the determinant factor is whether all of these complexes can be adsorbed onto the electrode at the chosen solution pH and accumulation potential. In most cases only some of these complexes can adsorb under the chosen conditions and the reduction potential for each complex will be specific for each inorganic substance. It is important to note that, due to the formation of a complex, the reduction potential is shifted toward a more negative potential relative to that of the inorganic substance or of the complexing agent depending on whether the inorganic substance (e.g., a metal) or complexing agent is reduced during the negative potential scan. If complexes of more than one inorganic substance is adsorbed onto the electrode and give separate reduction peaks that do not overlap, it is possible to use this for multielement determination in a single sample solution, as demonstrated for nickel and cobalt in Figure 1. A more versatile example of this, which was recently reported, employs the use of two complexing agents for multielement determination of six

metals. The inclusion of oxine enabled the detection of copper, lead, cadmium, and zinc, while the presence of dimethylglyoxime also enabled detection of cobalt and nickel in the same solution. The wide range of complexing agents that have been successfully used for the AdSV determination of numerous inorganic substances are also listed in Tables 1–3.

### Choice of Accumulation Potential

In cases where peak overlap occurs, this problem can usually be overcome by varying the solution composition, such as pH, buffer concentration, or buffer component; or by careful choice of accumulation or adsorption potential. The choice of accumulation potential is influenced mainly by two factors: (1) the charge on the electrode surface, and (2) the oxidation state of the dissolved complex. The choice of a complexing agent which forms complexes with many inorganic substances may result in their adsorption at a chosen applied accumulation potential and leads to competition for sites on the electrode surface. In such instance, the use of a selective deposition strategy that employs an accumulation potential, ~100–300 mV more positive than the reduction potential(s) of the analyte(s), can be effective in minimizing or eliminating the competition.

In other cases, it is possible to take advantage of the possibility of some inorganic substances, specifically metal ions, to be amalgamated with mercury by applying a more negative potential than the reduction potential(s) of the analyte(s) during the adsorption step. This ensures the collection of only the amalgamated metals. After this, the potential is switched back to a more positive potential to enable the amalgamated metals to be reoxidized and complexed by the excess complexing agent in the solution.

**Table 3** Some catalytic agents that have been used for CAdSV determination of inorganic compounds

Catalytic agent	Inorganic element or compound	Complexing agent(s)	Working electrode(s)	Voltammetric mode	Detection Limit (nmol l <sup>-1</sup> )

		TTHA	HMDE	SW	0.29	
Molybdenum		Oxine	HMDE	DP	0.7	
		Oxine	MFE	SW	0.15	
		TC	HMDE	LS	0.011	

BO =  $\alpha$ -benzoinooxime; BP = 2,2'-bipyridine; BPH = *N*-benzoyl-*N*-phenylhydroxylamine; CA = chloranilic acid; DHN = 2,3-dihydroxy-naphthalene; DMG = dimethylglyoxime; DTPA = diethylenetriaminepentaacetic acid; HMMA = 4-hydroxy-2-methoxymandelic acid; MA = mandelic acid; NN = 1-Nitroso-2-naphthol; PC = Pyrocatechol; TC = 2(2'-Thiazolulazo)-*p*-crezol; TTHA = triethylenetetramine-nehexaacetic acid.

Then a negative potential scan is applied, thereby minimizing the interference from inorganic substances that do not form an amalgam. So, in this case, the electrode processes involved include adsorptive collection, followed immediately by reduction and amalgamation, reoxidation step, and finally the repetition of the reduction of the adsorbed complex. This approach has been successfully used for the determination of antimony in the presence of iron, vanadium, and uranium, which is usually difficult to achieve, especially in the presence of high uranium concentration.

#### Choice of Electrodes for AdSV

Hanging mercury drop electrode (HMDE) is by far the most commonly used electrode for AdSV, as

indicated in Tables 1 and 3. This is because it has the ability to provide renewed (fresh) mercury surface and, hence, eliminate or minimize fouling caused by adsorption of interfering surface-active substances, or residual-adsorbed complex. The use of dropping mercury electrode (DME), when operating in the polarographic mode, has similar advantages and this electrode is commonly used for adsorptive polarographic determination of inorganic substances at higher concentrations. Also, in recent years, the use of mercury film electrodes (MFE) has also gained more interest in both AdSV and CAdSV (Tables 1 and 3) because of the environmental concern for mercury. Various microelectrodes and ultramicroelectrodes of different sizes and materials (usually plated with

mercury) have also been successfully used for the AdSV determination of some metals. More recently, the use of a bismuth film electrode for AdSV determination of some metals have been reported.

### Interferences in AdSV

The main interferences experienced in AdSV are usually caused by either competitive adsorption of surface-active substances, usually organic but can also be inorganic such as halide ions, or by competitive complexation of other metals by the chosen complexing agent. The latter can result, as indicated previously, in a competition for sites on the electrode surface and, consequently, result in a significant depression of the analytical response. The extent of interference depends on the relative affinities of the analyte and interferant(s) to the electrode surface and the concentration ratio of the analyte to the interferant(s).

Interference from surface-active compounds in AdSV can be removed by destruction of the organic substances prior to the voltammetric measurement by use of ultraviolet irradiation or by appropriate digestion in the presence of reagents, such as perchloric acid or hydrogen peroxide. Other approaches that can be used to reduce or eliminate interferences by inorganic and organic substances in stripping voltammetric measurements include the use of a more selective accumulation potential, use of shorter accumulation times, masking of interfering metals with ethylenediaminetetraacetic acid, more selective or specific choice of complexing agent, use of catalytic systems, medium exchange method, and quantification by standard additions method to compensate for matrix effects.

### Introduction

Cyclic voltammetry provides a profound insight into the redox reactions of organic molecules. In this technique, the potential is scanned from an initial

potential to an upper potential before reversing the direction of the scan and usually returning to the initial potential. The timescale of the experiment can be systematically varied by changing the scan rate  $v$ . This potential waveform has the advantage that the product of the electron transfer reaction that occurred in the forward scan can be probed again in the reverse scan. Thus, cyclic voltammetry can be used to determine formal redox potentials, to measure the rate of heterogeneous electron transfer kinetics across the electrode/solution interface and to detect

mercury) have also been successfully used for the AdSV determination of some metals. More recently, the use of a bismuth film electrode for AdSV determination of some metals have been reported.

### Interferences in AdSV

The main interferences experienced in AdSV are usually caused by either competitive adsorption of surface-active substances, usually organic but can also be inorganic such as halide ions, or by competitive complexation of other metals by the chosen complexing agent. The latter can result, as indicated previously, in a competition for sites on the electrode surface and, consequently, result in a significant depression of the analytical response. The extent of interference depends on the relative affinities of the analyte and interferant(s) to the electrode surface and the concentration ratio of the analyte to the interferant(s).

Interference from surface-active compounds in AdSV can be removed by destruction of the organic substances prior to the voltammetric measurement by use of ultraviolet irradiation or by appropriate digestion in the presence of reagents, such as perchloric acid or hydrogen peroxide. Other approaches that can be used to reduce or eliminate interferences by inorganic and organic substances in stripping voltammetric measurements include the use of a more selective accumulation potential, use of shorter accumulation times, masking of interfering metals with ethylenediaminetetraacetic acid, more selective or specific choice of complexing agent, use of catalytic systems, medium exchange method, and quantification by standard additions method to compensate for matrix effects.

### Introduction

Cyclic voltammetry provides a profound insight into the redox reactions of organic molecules. In this technique, the potential is scanned from an initial

potential to an upper potential before reversing the direction of the scan and usually returning to the initial potential. The timescale of the experiment can be systematically varied by changing the scan rate  $v$ . This potential waveform has the advantage that the product of the electron transfer reaction that occurred in the forward scan can be probed again in the reverse scan. Thus, cyclic voltammetry can be used to determine formal redox potentials, to measure the rate of heterogeneous electron transfer kinetics across the electrode/solution interface and to detect

chemical reactions that precede or follow electron transfer. Electrochemistry has several advantages over spectroscopy in that it provides 'direct' information about electron transfer and coupled chemical reactions. Moreover, it enables analysis to be performed in colored solutions without the significant problem of a large background absorbance typically found with ultraviolet-visible absorbance spectroscopy. Also, with the development of microelectrodes, voltammetry can now be performed in unusual media such as nonpolar solvents, supercritical fluids, gases, and even solids.

Many significant electrochemical events, such as electron and proton transfers, ligand exchanges, isomerizations, and ejection of leaving groups, occur on the low microsecond and nanosecond time domains. To achieve a meaningful insight into these redox processes, it must be possible to measure rate constants under a wide range of experimental conditions, such as driving force, temperature, etc. However, conventional electrochemical methods cannot fulfill this role since they are restricted to millisecond, or longer, timescales. Thus, while modern laser-based spectroscopy has provided a powerful new insight into chemical processes that occur at picosecond and even femtosecond timescales, it is only recently that electrochemists armed with electrodes of micro- or even nanometer dimensions, have meaningfully probed redox processes occurring on the submicrosecond timescale.

These attractive features of the technique, together with the wide variety of organic compounds shown in Tables 1 and 2 that can be reduced or oxidized, mean that cyclic voltammetry has truly come of age in the electroanalysis of organic compounds.

## Heterogeneous Electron Transfer Dynamics

Measuring the rate of heterogeneous electron transfer across a metal/solution interface is of considerable technological importance in areas ranging from electrosynthesis to the detection of highly reactive organic intermediates. At short times, i.e., large scan rates, the diffusion layer thickness is much smaller than the electrode radius and the dominant mass transport mechanism is planar diffusion. Provided that ohmic drop is absent and that the faradaic and capacitive currents can be separated, under these conditions, kinetic parameters can be extracted from the scan rate dependence of the separation between the anodic and cathodic peak potentials. Figure 1 illustrates a typical example of the effect of increasing scan rate on the voltammetric response for

anthracene. This figure shows that at high scan rates the time constants of the experiment and heterogeneous electron transfer become comparable and the peak-to-peak separation,  $\Delta E_p$ , exceeds the 57/mV expected for an ideal reversible electrochemical reaction. In the case of anthracene, heterogeneous electron transfer is a fast process since there is little difference in the molecular structure of the reduced and oxidized forms. Probing this rapid electron transfer reaction can be accomplished using fast scan rates, typically tens of thousands of volts per second, that is only possible using microelectrodes. The standard heterogeneous electron transfer rate constants for several organic molecules are given in Table 3. These data show that the rate of electron transfer across the electrode/solution interface is very significantly influenced by the identity of the redox couple. These variations reflect differences in the strength of electronic coupling between the electrode and the reactant as well as activation barriers that exist for the individual systems. For example, where the structure of the molecule is significantly distorted by the redox reaction, or where the reaction involves multiple steps, standard heterogeneous electron transfer rate constants as small as  $10^{-9} \text{ cm s}^{-1}$  can be observed, i.e., almost 10 orders of magnitude smaller than that found for the polyaromatic anthracene molecule.

A useful strategy in trying to extend the upper limit of measurable electron transfer rate constants is to perform measurements at lower temperatures. This strategy is successful because even for heterogeneous electron transfers with negligible inner sphere reorganization energies, activation barriers  $\sim 20\text{--}25 \text{ kJ mol}^{-1}$  are expected. Therefore, considerably slower rates of heterogeneous electron transfer are observed even by decreasing the temperature of the electrochemical cell by a few tens of degrees. Measurements of this type are greatly facilitated by microelectrodes since solvents, such as alcohols or nitriles that remain liquid over a wide temperature range can be used without catastrophic ohmic effects and the behavior of organic molecules such as *o*-nitrotoluene and nitrometisylene have been investigated.

## Homogeneous Chemical Kinetics

Adding or removing an electron from an organic molecule often creates a radical species that is not indefinitely stable and tends to react either with the parent molecule or other species in solution. For example, electrochemical oxidation of ascorbic acid (vitamin C) produces an oxidized product that

subsequently reacts with water to yield electrochemically inactive dehydroascorbic acid.

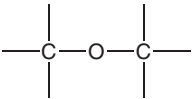

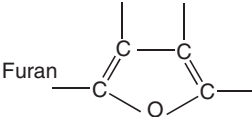

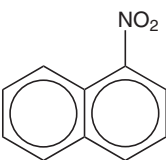

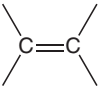

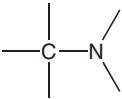

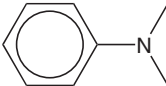

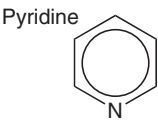

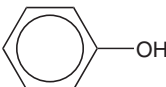

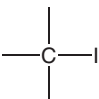

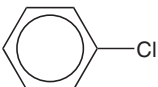

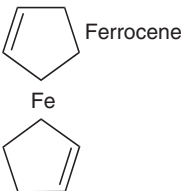

As shown in **Figure 2**, the voltammetric response is significantly altered by the coupled chemical reaction and thus allows the energetics and dynamics of these homogeneous chemical reactions to be probed. This figure shows that as the scan rate is increased, the contribution from the homogeneous reaction becomes less pronounced and the voltammogram approaches the shape of that for an electrochemically reversible process. The fact that ascorbic acid is electroactive means that its concentration in fruit juices can be determined without interferences from the coloration of the sample.

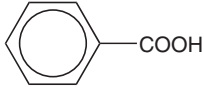

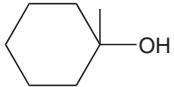

In general terms, coupled mechanistic schemes are described by the letters E (electrochemical) and C (chemical). The order in which they are written denotes the order in which the processes occur. Thus an ECE mechanism describes a process in which an electrochemical step is followed by a chemical step, which is then followed by an electrochemical step. A chemical step is a step where no electron transfer to or from the electrode takes place. Such a step does not by itself produce a charge flow into or out of the electrode and thus is not directly observable by an external measuring circuit. It may, however, influence charge flow because of other steps in the mechanism, which can be detected indirectly. The chemical step is not directly influenced by the electrode potential. An electrochemical step on the other hand involves electron flow to and from the electrode and as such produces a flow of charge that can be monitored by the external measuring circuit.

Bimolecular reactions in solution cannot proceed faster than the rate at which molecules come into close contact. Thus, bimolecular rate constants

cannot exceed the diffusion limited rate constant that is  $\sim 10^9\text{--}10^{10} \text{ mol l}^{-1} \text{ s}^{-1}$  in most organic solvents. Since under semiinfinite linear diffusion conditions, the characteristic time of cyclic voltammetry is  $RT/Fv$ , where  $v$  is the scan rate, experiments performed at  $\text{MV s}^{-1}$  scan rates allow kinetic information, such as lifetimes that are close to the diffusion limit, to be obtained. Thus, by scanning sufficiently fast the following chemical reaction can be outrun, and the irreversible response observed at slow scan rates can be made electrochemically reversible at higher scan rates. This behavior is opposite to that expected when heterogeneous electron transfer is slow where the response would become increasingly irreversible with increasing scan rate. The ability to make the voltammetric response reversible means that the formal potentials of highly reactive species can be accurately measured. As shown in **Table 3**, using approaches of this kind, the dynamics of a wide variety of coupled chemical reactions have been probed.

<sup>a</sup> Dimension given is the radius of a microdisk electrode unless otherwise stated.

**Figure 2** Simulated voltammograms showing the behavior observed for an organic molecule, e.g., acetophenone, that undergoes a following chemical reaction upon oxidation. The electrode is a  $5 \mu\text{m}$  radius platinum disk, and the rate constant for the homogeneous chemical reaction is  $7.6 \times 10^3 \text{ s}^{-1}$ .

Reductive coupling reactions are an example of a class of reactions where voltammetry has provided a deep insight into the reaction mechanism and allowed optimum conditions for electrosynthesis to be identified. The reductive formation of nucleophiles followed by an attack on an electrophilic center is also the basis for the synthesis of many heterocyclic compounds. For example, reducing the nitro group in suitable *ortho*-substituted nitro compounds to the

hydroxylamine stage may lead to an *N*-oxide of an *N*-heterocyclic compound. For example, *o*-nitrobenzalacetylacetone is reduced to 3-acetyl-2-methylquinoline-*N*-oxide.

On reduction of aryl halides, the initially formed radical anion decomposes to halide ion and the aryl radical; the aryl radical is generally more easily reduced than the substrate or it may abstract a hydrogen atom from the solvent system, but in suitably substituted compounds the radical may attack a phenyl ring with ring closure. Thus, for example, 5-(2-chlorophenyl)-1-phenylpyrazole is reduced to pyrazolo[1,5-*f*]phen-anthridine.

Oxidation of parent organics has also been extensively investigated using voltammetry leading to both anodic substitution and coupling. For example, the voltammetry of a large number of heterocyclic derivatives has been probed and compounds prepared through the anodic methoxylation of acylated heterocycles, in peptidomimetics, and in the first example of combinatorial electrochemistry.

A second voltammetric approach to probing the dynamics of homogeneous chemical reactions that are coupled to electron transfer is to exploit the

**Table 4** Rate constants for homogeneous chemical reactions involving organic compounds

<sup>a</sup>Dimension given is the radius of a microdisk electrode unless otherwise stated.

steady-state response observed at relatively slow (hundreds of milliseconds) at ultrasmall, i.e., micro- to nanometer, dimensioned electrodes. Steady-state measurements using electrodes of different radii can provide a powerful insight into the kinetics of some classes of homogeneous reactions since the limiting current density depends on the magnitude of the homogeneous rate constant (Table 4). Hence, coupled chemical (C) and electron transfer (E) reactions, e.g., CE mechanisms, catalytic follow-up processes, as well as reactions involving disproportionation have been characterized. It is important to note that reactions, such as chemical reactions that follow electron transfer (EC) mechanisms, cannot be investigated in the same way since the current density is not influenced by the following chemical reaction. In these circumstances, the homogeneous reaction does not affect the height or shape of the reversible steady-state voltammogram. However, as indicated by Figure 3, the position of the wave on the potential axis depends on the homogeneous reaction rate and kinetic information can be obtained by probing how  $E_{1/2}$  depends on the electrode radius.

The technique is best applied to reactions whose rate constants are of the same magnitude as  $D/r^2$ , where  $D$  is the diffusion coefficient of the analyte through solution and  $r$  is the electrode radius. Therefore, given that it is now feasible to fabricate microelectrodes with submicron critical dimensions, the dynamics of first order chemical reactions with rate constants between  $10^2$  and  $10^4 \text{ s}^{-1}$  can be investigated.

The redox properties of the vast majority of organic compounds are investigated at pristine surfaces such as highly polished platinum, gold, and glassy carbon electrodes. However, surfaces may be modified in many ways to get better catalytic effects, chiral

**Figure 3** Dependence of  $E_{1/2}$  for an EC reaction on the logarithm of the electrode radius.

induction, or some other desirable effect not obtainable at the 'classical' electrode materials. Irreversible adsorption, covalent attachment, and electropolymerization have been used. The modified electrodes are usually not stable enough for preparative reactions using high current densities but find common application as sensitive and selective sensors.

## Biologically Relevant Molecules

Voltammetry provides a useful tool for studying redox chemistry of the molecules relevant to biological redox reactions. Many proteins are exclusively involved in intraprotein electron transfer and typically function in ordered structures such as mitochondria. Under these circumstances, the redox

active centers are generally accessible on the outer surface of the protein. In contrast, the redox reactions catalyzed by oxidoreductases involve small molecules and two redox couples, i.e., the substrate and the cofactor or cosubstrate, participate in the reaction. Because the catalytic center of the enzyme is often located deep within the protein, it often undergoes only a very weak electronic interaction with the electrode. This weak coupling results in very slow heterogeneous electron transfer. Driven in part by their ability to selectively catalyze reactions of analytical importance, e.g., oxidation of lactate and glucose, a major objective is to create redox active films on electrodes that are capable of efficiently mediating electron transfer between the active site and the electrode. **Figure 4** illustrates the electron transfer coupling scheme where the enzymatic reaction for the oxidation (or reduction) of the substrate, S, is linked to the electrochemical reduction (or oxidation) of the mediator ( $M_{Ox}/M_{Red}$ ). The enzyme-catalyzed electrochemical oxidation (or reduction) of the substrate is called bioelectrocatalysis. A variety of oxidoreductases including oxidases as well as dehydrogenases can be 'electrochemically wired' to electrodes in this way allowing a wide range of otherwise electrochemically inactive substrates to be detected. This approach of using voltammetry at modified electrodes underpins the development of the disposable glucose sensor.

The challenge in this field is to control both the physical architecture and chemical reactivity of the film so as to promote selected electron transfer reactions while inhibiting others. With polymer-modified electrodes (PMEs), the electrode is conferred with the molecular selectivity and specificity that is lacking at a conventional pristine electrode. For example, poly(4-vinyl)pyridine and poly(*N*-vinylimidazole) can be functionalized with osmium and ruthenium polypyridyl complexes. These synthetic macromolecules act as useful model systems for

**Figure 4** Schematic structure of a bioelectrocatalytic film on an electrode surface. S is the substrate, P the product,  $E_{Ox}$  and  $E_{Red}$  are the oxidized and reduced forms of the enzyme,  $M_{Ox}$  and  $M_{Red}$  are the oxidized and reduced forms of the mediator.

understanding processes that occur in biological systems such as proteins. Proteins regulate processes that occur at reactive centers by controlling the dynamics or energetics of the reactions. For example, while the metal center may control the thermodynamics of a process (e.g., through its redox potential or excited state properties), the protein controls the kinetics.

Redox active polymer films are ideally suited to tackling these issues. The properties of many of these electroactive polymers, e.g., their conductivity, charge distribution, shape, etc., can be changed in a controlled and reproducible way in response to environmental stimuli, e.g., a change in the nature of the contacting solution, an applied voltage, light intensity, or mechanical stress.

## Voltammetry as a Tool for Synthesis

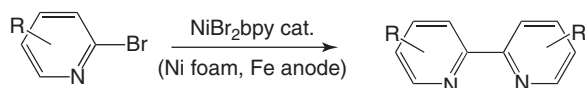

As discussed above, voltammetry allows electrons to be selectively introduced or removed from organic molecules. Therefore, it is an ideal approach for reversing the polarity of known functional groups and triggering reactions that would be difficult to drive thermally with the required degree of selectivity. For example, as illustrated in **Figure 5**, electrons can be added to electron-poor functional groups in order to convert them from electrophiles into nucleophiles. Alternatively, by poisoning the electrode at a sufficiently positive potential, electrons can be removed from electron-rich functional groups in order to convert them from nucleophiles into electrophiles. The ensuing reactive intermediates can then be trapped in order to complete reactions that involve the net coupling of either two electrophiles or two nucleophiles in ways that would otherwise be impossible. Reactions of this kind will play increasingly important roles in the construction of ever more complex 'supermolecules' and supramolecular assemblies.

For example, voltammetry has provided a mechanistic insight into the nickel-catalyzed homocoupling of halopyridines that results in significant improvements in the overall yield and product purity. Also, voltammetry has demonstrated the usefulness of sacrificial iron anode to produce iron ions that

**Figure 5** Creation of nucleophiles from electrophiles by voltammetric injection of electrons followed by reaction to yield desired product.

could complex the product, thereby allowing the nickel to reenter the catalytic cycle.

The development of lanthanides as one-electron reducing agents also depended critically on voltammetry. Electrochemical investigations provided a simple and systematic means to screen the properties of redox active species allowing the optimum reagent, i.e., formal potential and fast electron exchange dynamics, to be identified for specific applications. For example, in the case of samarium(II) diiodide, cyclic voltammetry was used to determine that ligand exchange occurs between triflate and iodide when samarium(III) triflate is mixed with the tetrabutylammonium iodide (TBAI) being used as the supporting electrolyte.

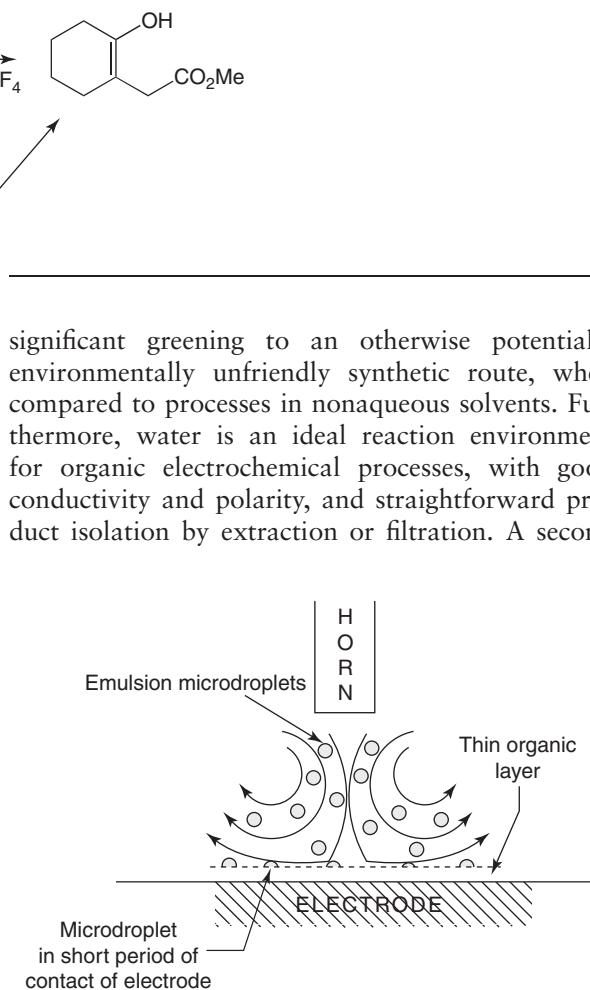

## Solvents and Electrolytic Media

Protic solvents continue to be used and new solvents, with unusually low nucleophilicity, high ionizing power, and high hydrogen bonding strength, making them good solvents for cation radicals, continue to be developed. Aprotic media are also widely used for investigating electrode reactions and synthesis. For oxidations acetonitrile (MeCN) with sodium perchlorate as supporting electrolyte or methylene chloride, sometimes with added trifluoroacetic acid and its anhydride to remove nucleophiles, has been used when MeCN was too nucleophilic and reacted with the intermediates. Liquid sulfur dioxide offers a solvent with very low nucleophilicity, but typical supporting electrolytes have only a limited solubility. For reductions *N,N*-dimethylformamide (DMF), MeCN, and dimethylsulfoxide (DMSO) have been used as media in which to perform voltammetric investigations. MeCN is slightly more acidic than DMF and DMSO, but less likely to lose hydrogen by atom abstraction.

Organic solvents may be undesirable, especially for industrial applications, and emulsions may

present an alternative. Emulsions may be simple emulsions: 'water-in-oil' or 'oil-in-water' or a 'bicontinuous microemulsion'. Such bicontinuous microemulsions are nontoxic, have a large interfacial area facilitating an intimate mixing of polar and nonpolar reagents, and high conductivity. Acoustic emulsification represents a pioneering development in the field of 'clean' technology for electrosynthesis using organics. There are generally two options by which sonoemulsion electrosynthesis may be achieved. The first involves suspending depolarizers as droplets in water, which, as illustrated in **Figure 6**, under sonication are forcefully transported to the electrode surface by acoustic streaming processes. This process may facilitate otherwise impossible voltammetry to be carried out, for example, by achieving dramatically higher mass transport rates or by removing pacifying material from the electrode surface. This approach has the additional advantage that the 'oil-in-water' emulsion that is produced provides a

**Figure 6** Schematic representation of the thin film and droplet deposits that govern the sonoelectrochemical response for electrochemical processes in acoustic emulsion systems.

sonoemulsion electrosynthetic approach applies solely for the case of a solid electroactive compound, and consists of dissolving the depolarizer in a nonaqueous solvent, which is then emulsified with an aqueous solution as described previously.

The advantages of utilizing sonoemulsion media in which to undertake voltammetric investigations or indeed perform electrosynthesis include the following. First, the resulting emulsions are extremely stable, precluding the need for surfactants. It is believed that this stability is due to the monodisperse nature of the emulsions and to the formation of an electric double layer around the suspended droplets. Second, the separation of products from the starting materials is facile: removing the acoustic field (by, for example, switching off the ultrasonic transducer) permits the separation of two immiscible phases. The organic phase is likely to contain the products of the electrosynthetic transformation, which can then be extracted and analyzed by conventional techniques. This method permits synthesis in the absence of environmentally unfriendly nonaqueous solvents. Third, there is a large surface area for electrochemical reactions to occur.

The electrochemical reduction of unsaturated organic compounds to paraffins is usually undertaken in nonaqueous solutions. However, the use of ultrasound allows voltammetry to be performed in a more ecofriendly manner by using a sonoemulsion of the substrate in water, so eliminating the need for the nonaqueous solvent. For example, voltammograms for the reduction of diethylmaleate, diethylfumarate, and diethylacetylene dicarboxylate in the form of microscopic droplets generated by applying power

ultrasound to aqueous electrolyte media are sigmoidally shaped, indicating well-behaved responses, even at the very high rates of mass transport applied in the presence of ultrasound. These reactions correspond to the following processes:

This approach offers the possibility of investigating the voltammetric properties of organic molecules in media in which they are essentially insoluble.

## Introduction

Gases that react chemically with solutions or solid reagents can be determined by absorption methods. Absorption in specific reagents is the basis for separation of a mixture of gases into its individual components that are then determined by different

methods. Volumetric analysis is one of the oldest techniques that are still in use.

## General Principles

The basic principle of the volumetric system of analysis is that a measured volume of sample, at a constant temperature and pressure, is exposed in a closed vessel to a suitable solid or liquid reagent that absorbs one or more of the constituents of the sample. The extent of the loss in the sample is determined by returning the sample to its original pressure and measuring the decrease in volume. The method is based

sonoemulsion electrosynthetic approach applies solely for the case of a solid electroactive compound, and consists of dissolving the depolarizer in a nonaqueous solvent, which is then emulsified with an aqueous solution as described previously.

The advantages of utilizing sonoemulsion media in which to undertake voltammetric investigations or indeed perform electrosynthesis include the following. First, the resulting emulsions are extremely stable, precluding the need for surfactants. It is believed that this stability is due to the monodisperse nature of the emulsions and to the formation of an electric double layer around the suspended droplets. Second, the separation of products from the starting materials is facile: removing the acoustic field (by, for example, switching off the ultrasonic transducer) permits the separation of two immiscible phases. The organic phase is likely to contain the products of the electrosynthetic transformation, which can then be extracted and analyzed by conventional techniques. This method permits synthesis in the absence of environmentally unfriendly nonaqueous solvents. Third, there is a large surface area for electrochemical reactions to occur.

The electrochemical reduction of unsaturated organic compounds to paraffins is usually undertaken in nonaqueous solutions. However, the use of ultrasound allows voltammetry to be performed in a more ecofriendly manner by using a sonoemulsion of the substrate in water, so eliminating the need for the nonaqueous solvent. For example, voltammograms for the reduction of diethylmaleate, diethylfumarate, and diethylacetylene dicarboxylate in the form of microscopic droplets generated by applying power

ultrasound to aqueous electrolyte media are sigmoidally shaped, indicating well-behaved responses, even at the very high rates of mass transport applied in the presence of ultrasound. These reactions correspond to the following processes:

This approach offers the possibility of investigating the voltammetric properties of organic molecules in media in which they are essentially insoluble.

## Introduction

Gases that react chemically with solutions or solid reagents can be determined by absorption methods. Absorption in specific reagents is the basis for separation of a mixture of gases into its individual components that are then determined by different

methods. Volumetric analysis is one of the oldest techniques that are still in use.

## General Principles

The basic principle of the volumetric system of analysis is that a measured volume of sample, at a constant temperature and pressure, is exposed in a closed vessel to a suitable solid or liquid reagent that absorbs one or more of the constituents of the sample. The extent of the loss in the sample is determined by returning the sample to its original pressure and measuring the decrease in volume. The method is based

on the Amagat law

$$\frac{V_i}{V} = \frac{n_i}{\sum_i n_i} \quad [1]$$

where  $V$  is the whole volume,  $V_i$  and  $n_i$  are the partial volume and mole fraction of component  $i$ . The partial volume of each component is proportional to its mole fraction.

The gas content in the mixture, expressed as the volume fraction and given in percent ( $p$ ), can be calculated from the relationship

$$p = \frac{V_a - V_b}{V_a} \times 100 \quad [2]$$

where  $V_a$  is the gas volume prior to absorption and  $V_b$  is the volume after absorption.

If the results are obtained at different working conditions and are to form the basis for precise, general predictions, the volume data must be reduced to standard (normal) temperature ( $0^\circ\text{C}$ ) and pressure (101 325 Pa). Thus,

$$V_0 = \frac{p_t V_t}{p_0(1 + t/273.15)} = \frac{p_t V_t \times 273.15}{p_0(t + 273.15)} \quad [3]$$

where  $V_0$  is the corrected volume,  $V_t$  is the observed volume,  $p_t$  is the barometric pressure (Pa),  $p_0$  is the standard pressure (101 325 Pa), and  $t$  is the temperature in degree celsius.

This relationship is valid only for dry gases. If the gas is saturated with water vapor from the confining fluid, the contribution of the water vapor to the total pressure must be taken into account. The relationship for reduction of the gas volume to standard conditions then has the final form

$$V_0 = \frac{p_t - p_{\text{H}_2\text{O}}}{p_0} \times \frac{V_t \times 273.15}{t + 273.15} \quad [4]$$

where  $p_{\text{H}_2\text{O}}$  is the water vapor pressure of the confining fluid at the temperature of measurement ( $t$ ).

In volumetric gas analysis it can be assumed that deviations from the ideal behavior do not introduce significant errors when molecular weights are small (e.g.,  $\text{O}_2$ ,  $\text{N}_2$ ,  $\text{CO}$ ,  $\text{CH}_4$ ). Only for hydrocarbons with more than two carbon atoms and for carbon dioxide must a correction be made according to Table 1.

## Confining Fluids

A gas may be quantitatively transferred from one chamber to another by displacing it with a liquid. There are two basic requirements for a confining liquid. It must not dissolve the gas to be determined or chemically react with it, and its viscosity and

**Table 1** Weights of 1000 ml of certain gases at  $0^\circ\text{C}$  and 101 325 Pa

Gas	$\text{g l}^{-1}$
$\text{CO}_2$	1.9632
$\text{C}_2\text{H}_6$	1.3408
$\text{C}_2\text{H}_4$	1.2507
$\text{C}_2\text{H}_2$	1.1608
$\text{C}_3\text{H}_8$	1.9660
$\text{C}_3\text{H}_6$	1.8665

wetting of glass must be low. The best confining fluid is mercury: its vapor pressure is extremely low and it is inert (although chlorine, bromine, hydrogen sulfide, and sulfur dioxide are exceptions to this rule). Mercury also has drawbacks: it is quite dense, it is poisonous, and it is expensive. Thus, it is often replaced by various salt solutions, even though these solutions do not completely fulfill the above conditions. In most of these aqueous solutions gases are absorbed (although to a limited degree).

Often a 22% (w/v) solution of sodium chloride, acidified with a little sulfuric or hydrochloric acid and colored with methyl orange or methyl red, is used. This procedure greatly decreases the solubility of certain gases (especially carbon dioxide). Before the analysis it is necessary to saturate the confining fluid by the gas to be analyzed. If this precaution is taken the errors caused by solubility losses are less than is commonly supposed.

## Absorption Reagents

The individual gases are absorbed in absorption reagents, which are solutions or solid substances. The chemical reaction on which the absorption is based must be sufficiently fast, quantitative, and selective, and the absorption capacity of the reagent must be sufficiently large.

For carbon dioxide, a 25–40% solution of potassium hydroxide has been recommended. The 25% solution is least viscous and it absorbs  $\sim 40$  ml of  $\text{CO}_2$  per milliliter. Potassium hydroxide is always preferred to sodium hydroxide, as the potassium carbonate formed is more soluble than sodium carbonate. This reagent dissolves all acid gases, which must be removed before the determination of  $\text{CO}_2$ . In the presence of other water-soluble gases solid reagents must be used over mercury as the confining fluid for this determination. A typical example is ascarite (asbestos soaked with sodium hydroxide).

Unsaturated hydrocarbons are mostly absorbed in 'activated' sulfuric acid, i.e., acid with dissolved silver or mercury(II) sulfate, which does not dissolve

saturated hydrocarbons. Often, fuming sulfuric acid is also recommended, but higher alkanes such as propane or butane are also dissolved:

A solution of potassium bromide nearly saturated with bromine dissolves all unsaturated hydrocarbons but it also dissolves traces of saturated hydrocarbons of C<sub>3</sub> and above:

A number of reagents have been recommended for oxygen. The reagent most often used is an alkaline solution of pyrogallol. The solution is usually prepared directly in the absorption pipette with constant bubbling with nitrogen to prevent the entrance of air. The absorption capacity of alkaline pyrogallol solution is ~12 ml of O<sub>2</sub> per milliliter. The absorption is rapid in any mixture where the oxygen content is less than ~20%. It is known that pyrogallol solution has a tendency to form carbon monoxide when the solution is exhausted or if it is insufficiently alkaline.

Oxygen can also be absorbed in an alkaline solution of sodium dithionate:

It evolves no gases, but absorption is slower than in an alkaline pyrogallol solution. It can be accelerated by the addition of sodium anthraquinone-2-sulfonate or indigo carmine.

The strong reducing power of chromium(II) chloride solution in an acidic medium is the basis of a reagent for oxygen absorption, based on oxidation of chromium(II) to chromium(III):

It does not dissolve acidic gases (carbon dioxide, hydrogen sulfide). If the pH is too low, chromium(II) slowly reduces hydrogen ions:

For this reason it is advisable to prepare chromium(II) chloride solution in a weak acid solution (e.g., acetic acid).

Moist yellow phosphorus is used to determine higher oxygen concentrations. This reagent has enormous capacity and can be used for oxygen contents up to 60%:

As the yellow modification of phosphorus is readily converted to the red form in the presence of light, the reagent must be protected in brown glass pipettes. Small quantities of unsaturated hydrocarbons inhibit the reaction.

Ammoniacal copper(I) chloride is an excellent absorption reagent and can be used to determine oxygen in concentrations of over 80%, provided carbon monoxide, unsaturated hydrocarbons, and acidic gases are absent.

The usual absorption reagent for carbon monoxide is a solution of copper(I) chloride in acidic, neutral, or ammoniacal medium. The absorption involves the formation of a coordination compound:

This reaction is an equilibrium, so it is impossible to remove the last traces of carbon monoxide with a partially exhausted reagent. Thus, absorption is carried out in several absorption pipettes to ensure quantitative absorption of carbon monoxide. The most commonly used absorbent is an ammoniacal solution of copper(I) chloride that contains ammonium chloride. This solution is stored over metallic copper. Instead of copper(I) chloride, copper(I) sulfate can be used. Its efficiency can be increased by addition of 2-naphthol. The addition compound formed, Cu<sub>2</sub>SO<sub>4</sub>·2CO, is more stable than the corresponding chloride.

Carbon monoxide can also be absorbed in a suspension of iodine pentoxide in fuming sulfuric acid, and oxidized to carbon dioxide:

Other gases are absorbed and determined by volumetric methods only in special cases. A solution of palladium(II) chloride or colloidal palladium and picric acid absorbs hydrogen, a solution of potassium dichromate is used for sulfur dioxide, and a solution of cadmium acetate or alkaline solution of hydrogen peroxide for hydrogen sulfide.

## Combustion Analysis

For gases that cause difficulties in absorption volumetric analysis (for which there is no suitable

absorption agent), combustion methods of analysis are employed. They are used primarily to determine hydrogen and saturated hydrocarbons. Combustion methods are based on total oxidation to water and carbon dioxide. The water formed is condensed and has a negligible volume (e.g., 100 ml of hydrogen is burned to form only 0.07 ml of liquid water) and carbon dioxide is determined by absorption in potassium hydroxide. The composition of the sample is calculated on the basis of the change in the volume of the sample and determination of carbon dioxide

The total contraction in volume after combustion of one volume of hydrogen is 1.5, in the case of methane it is 2.0, and for ethane it is 2.5.

The necessary oxygen must be provided either as air or better as pure oxygen or bonded in a metal oxide. Combustion can be carried out in three ways: explosion, slow combustion, and fractional combustion. The simplest technique for total combustion is explosion. A mixture of the gas sample and known amount of oxygen is ignited by an electric discharge. The slow combustion technique utilizes the catalytic effect of a hot platinum or palladium spiral. Today, fractional combustion is usually performed by means of copper(II) oxide or 'Hopcalite' (mixture of silver oxide, mercury(II) oxide, and silver permanganate). The oxygen required is supplied directly by metallic oxides, i.e., solid substances, resulting in considerable simplification in the analysis, both in the experimental arrangement and in the calculation of the contents of the individual gases. The reaction occurs according to

The relatively large differences in the combustion temperatures permits quantitative separation of some gas mixtures (hydrogen, carbon monoxide, methane).

It is evident that absorption reagents are not very selective and then the suitable choice of absorption reagents and, mainly, the order in which the individual gases are to be determined, are important. If complete analysis of common industrial gases by a volumetric method is of interest, then the following procedure must be employed. First, carbon dioxide is determined as it is readily soluble in all alkaline solutions, unsaturated hydrocarbons must be removed as the second component, and then

oxygen can be absorbed and determined by absorption of carbon monoxide. The other gases that are not absorbed (hydrogen, saturated hydrocarbons) can be determined by a combustion technique. The nitrogen content is found after removing the combustible components from the difference to 100%.

## Equipment

For exact measurement of gas volumes gas burettes can be used. In these burettes volume changes after absorption of gas in a suitable absorption reagent are also measured.

The classical burettes are the Hempel burette and the Winkler, Bunte, and Tutweiler burettes in various modified versions. The most widely used burettes are those employed in Orsat instruments (Figure 1). The burette consists of a glass cylinder graduated upwards from 0 to 100 ml. The water jacket surrounding the burette is generally sufficient to protect the burette from temperature changes. The sample is measured and the gas transferred to the absorption solutions using a confining fluid located in the leveling vessel. At the top is a stopcock so that the burette may be connected to the atmosphere (or to the source of the gas sample) or to any of the absorption pipettes.

Gases are sometimes absorbed directly in the burette (in the case of Bunte and Tutweiler burettes), but usually they are absorbed in absorption pipettes.

**Figure 1** Burettes employed in Orsat instruments: (A) common type; (B) for coal gas; (C) for mixtures of gases with high content of  $\text{CO}_2$ ; (D) for smoke gases.

**Figure 2** Absorption pipettes: (A) bubbler pipette; (B) Heinz pipette.

The prime function of the absorption pipette is to store the absorbent safely, away from contact with the atmosphere. Good absorption pipettes must be constructed so that absorption occurs over a large surface area, and is fast and quantitative. Some types of absorption pipettes employed in Orsat instruments are depicted in **Figure 2**.

For the complete analysis of gas mixtures the Orsat apparatus is commonly used. It consists of a volumetric burette with water jacket, leveling vessel, various numbers of absorption pipettes, and a quartz tube with pieces of copper(II) oxide or combustion pipette with a platinum spiral. This instrument is based on stepwise removal of the individual gases from the total sample volume, measured in a gas burette. Gooderham's modification is very interesting. The gas mixture continuously passes through a system of soap-film meters and absorption pipettes. The volume change after absorption in the individual absorption reagents is found from the change in the flow rate.

## Sources of Errors

The precision and accuracy of determinations by absorption volumetric analysis is influenced by the

system errors. Some of the factors directly affect the reading of the volume, while others are a result of the absorption process. There are three main sources of errors related to:

1. the confining fluid;
2. changes in temperature, atmospheric pressure, and vapor pressure; and
3. absorption reagents.

In the confining fluid, gases are physically dissolved according to Henry's law. The amount of gas dissolved in a given volume of liquid is proportional to the partial pressure of the gas. This is very important in the sampling and analysis. The confining fluid must be saturated with a particular gas mixture of a narrow range of composition. The data in **Table 2** provide a picture of the solubilities of various gases in water and brine solutions. To overcome the solubility of gases in absorption solutions it is also necessary to contact a small portion of the sample with all solutions immediately before the analysis.

Volumetric measurements are greatly dependent on temperature changes. A temperature change of  $1^{\circ}\text{C}$  produces a change of the volume of  $\sim 0.3\%$  (under isobaric conditions). To decrease this effect, the laboratory should at least face north to minimize temperature changes or be thermostatted or air-conditioned, and the measuring burette should be placed in a water jacket. In addition to direct volume changes, changes in the water vapor pressure can result from temperature fluctuations. If the dry gas sample is analyzed, then absorption is accompanied by an increase in the volume concentration of the water vapor corresponding to its vapor pressure at a given temperature, e.g., at  $20^{\circ}\text{C}$  this increase is  $\sim 2.3\%$  (see **Table 3**).

For analysis performed within a short period of time, it is assumed that the atmospheric pressure is constant. If the procedure of the analysis takes several hours or days (a pressure change of 133.32 Pa produces

**Table 2** Solubilities of various gases at  $20^{\circ}\text{C}$  in water and saturated NaCl solution (milliliter of gas in 1000 ml water at a partial pressure of 101 325 Pa)

**Table 3** Vapor pressure above water and some salt solutions

Temperature (°C)	Vapor pressure (Pa)		
	H <sub>2</sub> O	Sat. solution of NaCl	Sat. solution of Na <sub>2</sub> SO <sub>4</sub> ·10H <sub>2</sub> O
15	1700	1270	1600
20	2340	1740	2170
25	3170	2350	2930

a volume change  $\sim 0.13\%$ ), a compensator of the Pettersson type is used. However, it is more common to employ a suitable correction to the measured results using eqn [4].

One important factor, which can also be a source of errors, is the separation process. The absorption can be incomplete, because some absorption reagents are slow in their action. These errors can be avoided by using a suitable instrumental design of the absorption pipettes and repeated absorption in one or two absorption pipettes. In the analysis of a gas mixture it is very important to maintain an exact analysis order.

If the experimental conditions are suitably adjusted and the necessary correction is introduced, the error in determination by absorption volumetric analysis is in the range 0.2–2%.

## Volumetric Analyzers

Volumetric analyzers are basically mechanized Orsat instruments. They work periodically and are mainly used for determining a single component, usually carbon dioxide, sulfur dioxide, ammonia, hydrogen sulfide, hydrochloric acid, or acetylene. In some instruments there are also accessories for combustion, which permit the determination of combustible gases or analysis of mixtures such as  $\text{CO}_2 + \text{CO} + \text{H}_2$  or  $\text{CH}_4 + \text{CO} + \text{H}_2$ . Their sensitivity is relatively poor. They are most often used in plants for control of combustion processes.

### Introduction

Water is an essential resource for all living species, including man, and it is necessary to analyze a range of natural waters (e.g., seawater, rainwater, surface water, and groundwater), polluted waters (e.g., industrial water and sewage water), and purified waters (e.g., potable water and distilled water). This article presents an overview of sampling and sample treatment procedures and discusses a range of analytical techniques used for the quantification of major, minor, and trace constituents.

### Sampling and Sample Treatment

#### Sampling

The collection of water samples and subsequent sample treatment depend primarily on the type of water that is collected and the aim of the analysis. It is important that samples are collected in such a way that they are representative of the water body from which they are taken. This means that the concentrations of the determinand and interferences in the sample should not differ from the concentrations present in the original water body. The need for representatives may limit the volume of sample that may be collected; for example, to take into account a sharp gradient in analyte concentrations relatively small sample volumes may be taken without disturbing the original gradient.

Sample integrity is also very important. Care must be taken to prevent contamination of the sample or sorption of the determinand. Quality control procedures must be applied to guarantee that contamination or sorption has not occurred. Analysis of samples that have not been taken or stored properly is useless. Results of such analyses may lead to false data

and erroneous conclusions following interpretation of the results.

### Sample Preservation

Ideally samples should be analyzed *in situ* or at the site of sampling in the field. If direct measurements are not possible or are too expensive, samples should be analyzed as soon as possible to avoid the need for preservation. However, samples cannot always be analyzed directly and they may have to be stored for so long that preservation is necessary. The preservation of water samples is covered in ISO standard 5667/3 (1985). The preservation methods described in this standard include time limits for sample storage and analysis; specifications for container material; prevention of exposure to light; temperature control (2–5°C); pH control (addition of sulfuric, nitric, or phosphoric acid, or sodium hydroxide); addition of special reagents (e.g., ethylenediaminetetraacetic acid (EDTA), copper sulfate, zinc acetate, formaldehyde) to retard biological activity, hydrolysis of compounds and complexes; and measures for reducing volatility of compounds and sorption effects.

### Storage

As stated above, preservation and storage of samples should be avoided if possible. When storage is necessary, sample preservation by use of low temperatures is preferred to the addition of chemicals. Low temperature maintains sample integrity while the addition of chemicals may cause interferences or contamination in the sample. However, when samples are cooled, the determinand may crystallize or absorb on any precipitates that are formed; storage at 4°C is therefore preferred. Samples should be stored in chemically inert gas-tight containers of low adsorptivity and kept in the dark to prevent growth of bacteria and algae. Air contact is minimized by filling the sample bottle to the rim before closing. In this way the redox state can be kept stable for a longer period (no oxygen influence). Samples should be uniquely identified and storage conditions (duration, temperature, etc.) recorded to minimize the possibility of errors. Automated systems for laboratory management (e.g., laboratory information and management systems, barcodes for identification) are recommended.

### Pretreatment

Depending on the planned use of the results, pretreatment of the sample may be necessary. As matter initially suspended in the sample may agglomerate as solid matter, the suspended matter must be separated as soon as possible. This separation is most commonly done by filtration, which should ideally be

carried out directly after sampling at the sampling site. A 0.45 µm membrane filter is internationally accepted to achieve a separation between dissolved and suspended matter. Particles smaller than 0.45 µm can pass through the filter and are treated with the dissolved matter. These tiny particles may contain the greatest part of the trace constituents owing to their high adsorptivity and large surface area. Procedures have been designed to correct for the contributions made by small particles to the true dissolved content. The chances of contamination of sample during pretreatment are lower in the laboratory; pretreatment in the field requires some experience. When samples cannot be filtered in the field, they should be filtered on arrival in the laboratory. Addition of chemicals to dissolve a particular determinand from the solid phase generally causes contamination of the sample and increases the variability of the analytical result.

## Analytical Techniques

Water analysis is mostly conducted using physicochemical methods. A limited number of physical parameters (temperature, electrical conductivity, redox potential) and test parameters (such as color, smell, and taste) are measured in water analysis. Chemical/physicochemical methods can be used to analyze for a wide range of components, both inorganic and organic. Spectrochemical or electrochemical methods are mainly used for the analysis of inorganic constituents, while chromatographic methods are applied for the analysis of organic components.

### Physical and Physicochemical Analysis

Formerly, color, smell, and taste were assessed by sensorial testing by panels or experts. Color is now determined by spectrophotometric methods. Following a standard protocol, the extinction is determined at several wavelengths. The color characteristics can be quantified in an automated procedure.

Although it is generally thought that smell can only be estimated qualitatively, recent developments suggest that quantitative measurements are possible. In one method a series of seven dilutions of the sample is prepared with odor-free water. The series of samples, in which each sample is randomly paired with a blank, is offered in ascending order for testing by a panel of at least eight people. For each pair a panelist chooses which sample has the greatest odor. The results of the test are incorporated into a statistical evaluation procedure to determine the threshold dilution number. Interlaboratory variation of less than 20% is possible.

Taste can be determined similarly by organoleptic test panels. As for smell determination, considerable effort is required to obtain accurate results. Again,

interlaboratory variations of less than 20% are possible. As both smell and taste provide qualitative information, valuable indications are derived for analyzing the sample.

Temperature can be measured very easily by negative-temperature-coefficient resistors or temperature-sensitive transistors in small probes. These devices can also be combined with other sensors. Such combined sensors allow the direct correction of the measured parameter for temperature change.

The electrical conductivity can be measured over a wide range of concentrations. The size of the measuring cells is smaller than the apparatus used in the past. A wide range can be accommodated by using three-electrode measuring cells and automatic ionic strength adjustment of the frequency of the alternating current that is applied across the cell for phase-sensitive measurement. Alternating current is used to prevent polarization of the electrode surface. Electronic correction for temperature change is commonly applied in modern apparatus.

Measurement of redox potentials is relatively inaccurate. As the redox potential measurements are easily influenced by adsorption of organic substances such as minute amounts of oil, it is essential to clean the electrode surface. This is best done with a mixture of calcium carbonate, detergent, and trisodium phosphate.

The measurement of pH is a complex subject. Corrections have to be made for the temperature coefficient of the buffer solutions used for calibration of the meter and the difference between the temperature at which the instrument is calibrated and that at which the measurements are made. This is done using microelectronics. Efficient electrodes with high outflow of electrolyte from the reference electrode are used to overcome errors due to liquid junction potentials that may occur, especially in the case of low-ionic-strength water (de-ionized condensate, rainwater, etc.). To avoid the influence of carbon dioxide, ammonia, sulfur dioxide, etc., from the ambient air, a flow-through electrode in a flow-through system can be used for the pH determination. The latest development is the commercial production of ion-selective field effect transistor pH electrodes, which are much less fragile than pH electrodes with a glass membrane that is sensitive to acid. Glass electrodes are still very common. Because of the small size of these electrodes, smaller sample volumes are needed and measurements with probes are possible. This is an advantage, for example, in the *in situ* determination of groundwater or monitoring the pH of rainwater during showers.

Dissolved oxygen is now almost exclusively measured amperometrically with an oxygen electrode.

The apparatus is equipped with a potentiostat and a three-electrode system, which is separated from the sample by a membrane that passes oxygen to the inner compartment of the electrode. In the inner compartment there is a solution with an electroactive substance (usually bromide). A three-electrode measuring cell is used to allow stabilization of the response. A three-electrode system allows determination when an intermediary electroactive substance is used and for subsequent regeneration of this substance. Corrections for ionic strength and temperature can be made automatically. Dissolved organic substances such as phospholipids from microorganisms, detergents, and oil interfere because these substances reduce the permeability of the membrane.

### Groundwater Analysis

Generally, groundwater is sampled from filters in groundwater wells, where it is usually pumped up with an impeller pump. Before sampling, the filters are cleaned with the groundwater to be sampled. The volume of water used for cleaning is about three times the void volume of the filter and connection tube. Applying an under pressure to the well collects samples using this procedure. Often, solute gases like carbon dioxide are expelled, causing the pH of the sample to rise. Next, the sample is filtrated; for example, through a 0.45  $\mu\text{m}$  pore size cellulose nitrate membrane filter. Although it is internationally accepted that a pore size of 0.45  $\mu\text{m}$  can distinguish between suspended and solute substances, colloidal particles have been shown to cause problems here. These particles are solid and can easily slip through the 0.45  $\mu\text{m}$  membrane filters. The sorption of substances is also unpredictable when using filters. Furthermore, the transport of samples to the laboratory takes place under unconditioned circumstances and transport times are often long and variable. The pH shift, filtration, and variable transport times cause drastic changes in the chemical composition of the sample. The changes restrict the representativeness of the sample of groundwater originally present in the well.

Although the representativeness of the original groundwater may be poor, samples are still analyzed to obtain an impression of the condition of the groundwater. Since the chemical composition of groundwater highly resembles the composition of drinking water, groundwater is analyzed in almost the same way as drinking water. However, tritium is usually not measured when drinking water is analyzed. Tritium in groundwater can be used to assess the time groundwater needs to infiltrate the soil from surface level to the filter of a well. Tritium found in

groundwater originates from nuclear tests carried out from 1962 to 1965 (highest in 1963). Having been washed from the atmosphere through precipitation, the tritium ended up in groundwater. As the decay time of tritium is 12.43 years, its activity can be measured over a long time period. Transport times can be calculated from the time series for tritium monitored in a well filter. Although these transport times can be assessed from individual measurements, the accuracy is then much less. Tritium is measured through the decay products, electrons, and helium. Normally, beta radiation is measured to establish the concentration of tritium. Water containing tritium is concentrated to improve the accuracy of the measurements in groundwater. First, a portion of the sample is distilled to remove contaminants. This is followed by enrichment during a 5-day electrolysis of the sample. Sodium hydroxide is added to 150 ml of the sample to increase the conductivity. The sample is then placed in an electrolysis cell, and cooled in a freezer. To prevent absorption of water from the ambient air, the electrolysis cell is trapped on a zeolite absorption column. After electrolysis, 15 ml of the sample remains. This is converted to hydrogen through the reaction with elemental magnesium. The resulting tritium-containing hydrogen gas is catalytically converted with ethene to ethane, using platinum as catalyst. The gas is then brought into a proportional counter and activity counted. On each run, both a background sample and a sample with known activity are analyzed. An alternative way is to add the sample to a portion of degassed water and leave the sample aside for about half a year. Helium is formed and can be measured by mass spectrometry. From the result the amount of tritium original present the tritium concentration is derived.

### Inorganic Chemical Analysis

**Minor constituents** Interest in sensor techniques is growing in environmental analysis. Coupling of sensors with simple telemetric systems facilitates monitoring with remote fast data processing. Moreover, flexible monitoring networks can be realized because sensors are easily transportable. Possible changes in the sample between sampling and analysis and much logistical effort in carrying out analysis in the laboratory are obviated.

One of the most powerful methods available is ion chromatography (IC). In IC, separations are accomplished by passing a small volume (20–250  $\mu\text{l}$ ) of the sample through a column filled with a low-capacity ion-exchange resin. For anion chromatography, colloidal anion-exchange medium is agglomerated as a thin surface shell on sulfonated polystyrene-

divinylbenzene particles. The column is eluted with a sodium hydrogencarbonate/carbonate solution. After elution in a suppressor system, sodium is exchanged with hydrogen, by which hydrogencarbonate/carbonate is converted to carbon dioxide, which has low conductivity. By an analogous reaction, anions are converted to their respective acids, which can be detected conductometrically very sensitively owing to the high ionic mobility of the hydrogen ion in water. Concentrations as low as  $100\mu\text{g l}^{-1}$  can be determined without any treatment of the sample. IC is routinely applied for the determination of chloride, nitrate, and sulfate. Fluoride, nitrite, and phosphate are increasingly determined by IC. IC is less widely applied for the determination of cations, owing to the lower sensitivity of IC compared with atomic absorption spectrometric methods.

A serious problem with IC is insufficient separation. This occurs mostly in the analysis of samples with a complex matrix (e.g., in the presence of complexing organic molecules) like groundwater, percolation water from tipped refuse, potable water after ozonization or chlorination, or when substances are determined in extremely low concentrations. In the first case, sample pretreatment (e.g., addition of eluent, removal of constituents that are present in high concentrations, etc.) is necessary, but this increases the cost of analysis and there is an additional risk of contamination.

Flow-through methods are often applied in water laboratories and can be performed in segmented mode (2–3 mm bore with separation of samples in the tube effected by air bubbles) or in nonsegmented mode (0.3 mm bore). In flow-through systems the determinand is generally derivatized and the colored product is measured photometrically. The segmented system is usually designated as continuous flow (CF). The system working with nonsegmented streams is generally termed flow injection (FI). FI methods allow the samples and reagent zones to be manipulated under thermodynamically nonequilibrium conditions. This makes it possible to use unstable reagents and reaction products. The selectivity is enhanced by kinetic discrimination when the determinand can be measured selectively because of differences in reaction rate. Gradient calibration techniques can also be applied. Moreover, FI enhances the performance of an analytical method through the contamination-free handling environment (addition of reagents inside a closed system), use of small volumes of sample (typically 0.1 ml) and amounts of reagents, and precise sample injection. Apart from these advantages, the introduction of FI into a laboratory with a heavy workload is confronted with difficulties in applying kinetic methods because controlled mixing and

timing is required for the reagent addition and measurement stages. Accordingly, CF rather than FI methods are mainly used in routine laboratories and many methods are already available.

**Discrete analyzer** Discrete analyzer is increasingly applied for practical chemical analysis of water. The analyzers facilitate and speed-up sample processing and reagent handling. Continuous loading of samples increases the efficiency. Cooled reagent storage and the large cuvette allow increased throughput of samples.

The advantage of discrete analyzers is that sample crossover in the system itself is the lowest possible. Volumes of 75  $\mu\text{l}$  of reagent and sample volumes as large as 100  $\mu\text{l}$  are sufficient. In an automated system with a throughput of 200 determinations per hour in the same sample 6 to 10 components (such as ammonium, alkalinity, aluminum, boron, bromide, calcium, chloride, chromium(VI), cyanide, fluoride, iron, magnesium, nitrate, nitrite, phosphate, etc.) can be determined. In discrete analyzers normally conventional spectrophotometric methods are used. These methods are prone to interference of the matrix of the sample. As a good concept for interference studies still is not available, interferences are as yet not sufficiently studied systematically even for routine analyses.

Another promising alternative technique for the determination of anions is capillary zone electrophoresis (CZE). In this technique, a DC voltage (typically 30 kV) is applied over a capillary of typical dimensions 60 cm  $\times$  75  $\mu\text{m}$  filled with a buffer containing (among other things) chromate and an osmotic flow modifier (a proprietary cationic surfactant). The electroosmotic flow and electrophoretic mobility cause the separation of the ions. The separated ions displace chromate locally. When the stream is monitored photometrically, these displacements are registered as peaks whose areas are a measure of the concentration. This is an advantage compared with isotachopheresis (from which CZE is derived), in which the length of the signal plateau is a measure of the concentration. Less time is needed in CZE for a determination and standard chromatographic data-processing computers can be used. CZE can also be used for the determination of cations, in which case another ultraviolet (UV)-absorbing substance with optimal electrophoretic mobility is added and the polarity is switched. The sample volume is  $\sim 50$  nl and only small amounts of reagents are needed for analysis with CZE. The sensitivity is usually a factor of 1000 less than that of IC, but concentration by electromigration is possible. Although CZE is said to be matrix independent, sources of error have not yet been studied in any detail, but the technique seems

promising for efficient analysis of main components in several types of water (time of analysis 5 min; costs US\$20.00 per component).

**Standard methods** Chloride is still frequently determined titrimetrically (argentimetry with potentiometric endpoint detection). But chloride can also be determined in a flow-through system with photometric detection. Chloride releases thiocyanate from mercury(I) thiocyanate, which reacts with Fe(III) to form a colored complex.

Sulfate is still determined in CF systems with barium and a metallochromic indicator such as dimethylsulfonazo(III) (DMSA(III)) or methylthymol blue. As DMSA(III) is a metallochromic indicator, interfering cations should be removed prior to the determination step. Such pretreatment can be done in the flow-through system. The method suffers interference only from high concentrations of potassium, phosphate, hydrogen ion, chloride, and nitrate. As a consequence the method performs favorably when applied to groundwater, wastewater, or percolation water from tipped refuse.

Nitrate is commonly determined in a flow-through system through a Griess (diazo) compound after reduction to nitrite in a cadmium or copperized cadmium reduction column. The diazo-coupling reaction with nitrate is very selective. The reduction step is a major source of error; the reduction efficiency should be repeatable within 5% and be higher than 80% and this must be ascertained by frequent analysis of standards. In a CF system a throughput of 90 samples per hour is possible. The precision is better than 1.5% in the range 1.0–5.0  $\text{mg l}^{-1}$  nitrate. The method suffers interference from dissolved organic substances that produce a high background color in a sulfuric acid medium. Salinity and reactive chlorine compounds remaining after chlorination also affect the signal. Nitrate is also determined spectrophotometrically after reaction with diphenylamine with an excess of sulfuric acid.  $\text{NO}_2^-$ ,  $\text{ClO}_3^-$ ,  $\text{BrO}_3^-$ ,  $\text{IO}_3^-$ , Mn(VII), Cr(VI), V(V), Fe(III), and Mo(VI) interfere. For most types of water, however, the interference is often negligible since these components are not present in sufficiently high concentrations.

Nitrite may be determined through the reaction with sulfanilamide and *N*-(1-naphthyl)ethylenediamine in acidic solution. The lower limit of detection of this method is 30  $\mu\text{g l}^{-1}$  nitrite. Because of its simplicity and reliability, photometric detection is still preferred.

**Kjeldahl nitrogen** For a long time organically bound trivalent nitrogen was measured according to the method of Kjeldahl, where the water sample is

evaporated to dryness and digested with sulfuric acid. Potassium sulfate is added to elevate the destruction temperature. The destruction residue is neutralized and ammonium is measured to establish the Kjeldahl nitrogen content. To calculate 'organic nitrogen', the result of the determination of Kjeldahl nitrogen has to be corrected for the amount of ammonium present in the sample. Kjeldahl used mercuric ions to catalyze the efficient oxidation of protein-like substances. The intoxication caused to humans in Japan in the 1953–60 periods after ingestion of mercury-containing fish from the Minamata Bay gave an impulse to highly reduce the use of mercury in the laboratories. Through this incident, first mercury was replaced by cupric ions, and later, selenium was used as catalyst, although their effectiveness remained controversial. Next the use of catalysts was abandoned in favor of potassium peroxodisulfate. In this procedure sulfuric acid is added to the sample and the sample is evaporated. After cooling potassium peroxodisulfate is added for the destruction of organic matter. The residue then had to be warmed to a temperature of 370°C for completion of the destruction. The determination is completed by the measurement of ammonium. Despite its rationalization, this method remains very laborious. An alternative for the measurement of total nitrogen is the combustion of the sample in an argon–oxygen atmosphere in the presence of ceric oxide at 1000°C. The produced nitrogen oxides are converted to nitrogen oxide, which can be determined electrochemically or by chemoluminescence. In electrochemical detection, nitrogen oxide reacts with the nitrate ion at the working electrode. Chemiluminescent detection is achieved when nitrogen oxide reacts with ozone to form nitrogen dioxide with the emission of light. The amount of light, measured with a photomultiplier, is proportional to the amount of nitrogen present in the sample. This measurement takes about 3 min per sample.

Phosphate is mostly determined photometrically through the reaction with ammonium heptamolybdate in acidic medium in the presence of potassium antimonyl tartrate as a catalyst. 12-Molybdophosphoric acid is formed that upon reduction with, for example, ascorbic acid has a blue color. The lower limit of detection is  $10\text{ }\mu\text{g l}^{-1}$ . Chromium(VI), nitrite, and high concentrations of chloride and iron interfere. The lower recoveries caused by iron are eliminated by addition of hydrogensulfite.

Carbonate and hydrogencarbonate are determined by an acidimetric titration to endpoints of pH 8.35 for carbonate and pH 4.35 for hydrogencarbonate. The indicator electrode is usually a glass electrode that allows the pH to be followed potentiometrically. In one

mode, the titrant ( $0.01\text{ mol l}^{-1}$ ) is added at a constant rate and the pH is monitored continuously. Processing of the recorded data yields the endpoints. Automation of the determination is possible but expensive.

In modern laboratories fluoride is almost exclusively determined with a fluoride-selective electrode after addition of a total ionic strength adjustment buffer with citrate and cyclohexanediaminetetraacetic acid as decomplexing agents. The electrode signal suffers little interference from other ions. When fluoride has to be determined in concentrations as low as  $1\text{ }\mu\text{g l}^{-1}$ , application of the electrode in a CF apparatus is advantageous. Decomposition of metal–fluoride complexes is difficult and high recoveries are required (above 80%). Quality control is necessary. It may even be necessary to carry out the decomposition of the complexes outside the analyzer in order to increase the time available for the reaction. The method suffers interference from extreme pH and multicharged cations such as  $\text{Fe}^{3+}$  and  $\text{Al}^{3+}$ .

Ammonium is determined in many laboratories in a CF system in which the Berthelot reaction is implemented. In the Berthelot reaction, ammonium reacts with chlorine and phenol in the presence of sodium nitroprusside as catalyst in alkaline medium. EDTA is added to prevent interference of calcium and magnesium. Modern systems have been developed that use macroporous polytetrafluoroethylene (PTFE) membranes. In these systems a sample is introduced into a stream to which sodium hydroxide solution is added. Ammonia diffuses through the PTFE membrane into a stream of de-ionized water and the stream is fed through the flow-through cell of a conductivity meter. In this system a minimum of reagents is required and the only interference is from volatile amines.

The determination of hydrogen ions is important for rainwater. Hydrogen ion concentration is often calculated from the pH. However, this may increase the uncertainty (pH-to-hydrogen ion conversion is a logarithmic function) and decrease the accuracy because of the inaccuracy in the value of the activity coefficient (which is affected by temperature and ionic strength) that is required for the conversion from a measured activity to a calculated concentration. pH measurement therefore requires careful attention to the measuring conditions (temperature, ionic strength, avoidance of contact and diffusion potentials, etc.). Under such circumstances procedures such as Gran's plot or titrimetric methods are preferred to direct potentiometry.

Sodium and potassium are mainly determined by flame atomic emission spectrometry (FAES), flame atomic absorption spectrometry (FAAS), and inductively coupled plasma atomic emission spectrometry

(ICP-AES). FAES is widely used for the determination of potassium and sodium, but interference is experienced from stray light. In FAES and FAAS, ethyne (acetylene) and air are generally used as the flame gases. After acidifying the samples with nitric acid, an electron buffer (cesium chloride or lanthanum nitrate) is added to suppress interference by phosphate. When low concentrations (below  $50 \mu\text{l}^{-1}$ ) of potassium (in rainwater or boiler water) have to be determined, atomic absorption spectrometric methods are usually applied. For determinations at such low concentrations, sample containers and the nebulizer system must be scrupulously cleaned by soaking for  $\sim 24$  h in dilute nitric acid. FAAS is therefore preferred for low-concentration measurements. For sodium and potassium measurement in particular, simplified and cheaper AAS instruments can be used that are provided with a light source that is monochromatized with a filter instead of the more sophisticated hollow cathode lamp (HCL) or electrodeless discharge lamp (EDL). In matrix-free water samples such as boiler water, sodium can also be measured down to  $1 \mu\text{g l}^{-1}$  with an ion-selective electrode. The samples are not pretreated in most applications of ICP-AES. Samples with a high salt content can be reproducibly introduced with an ultrasonic nebulizer or must be diluted appropriately.

Calcium and magnesium are often determined by FAAS. Nitrous oxide and ethyne (acetylene) are the best flame gases. Prior to measurement the sample is acidified with nitric acid. Lanthanum nitrate is added to suppress interferences by oxidizable acids, aluminum and organic complexes of aluminum, phosphate, silicate, iron, etc. Strontium chloride can be used instead of lanthanum nitrate. To prevent ionization in the flame, cesium chloride, potassium chloride, or sodium chloride can be added. No pretreatment is used when the determinations are carried out with ICP-AES; because of the high temperature of the flame, all calcium phosphate compounds are decomposed. If a determination is needed only occasionally, calcium and magnesium can be determined titrimetrically with ethyleneglycol-bis (2-aminoethyl)- $N,N,N',N'$ -tetraacetic acid (EGTA) and Eriochrome Black T as indicator in alkaline medium. Magnesium is titrated first. Next, magnesium-EGTA complex is added and calcium displaces magnesium from this complex. The liberated magnesium is titrated as a measure of the calcium in the sample. Cyanide is added to overcome any effect of traces of iron and heavy metals.

Iron and manganese can be determined with FAAS; air and ethyne are used as flame gases. Prior to the determination of total iron and manganese, digestion

with aqua regia in a microwave oven for 1 h is required. This treatment takes care of refractory compounds such as iron oxides. Iron and manganese can also be determined with ICP-AES, in which case no predigestion is required owing to the high temperature of the flame.

Silicate is determined spectrophotometrically with ammonium molybdate and ammonium vanadate. The pH of the sample must be adjusted to 7–8. Potassium cyanide is added to prevent interference of heavy metals. Oxalic acid is added to destroy molybdophosphate and vanadophosphate and to bind aluminum in a complex. As in all spectrophotometric determinations, high and variable optical absorption of the sample (due to color or turbidity) at the wavelengths of investigation causes errors; tannin, iron, and sulfide also interfere. To avoid contamination, all contact surfaces should be of polyethylene. It is also possible to determine silicate using FAAS, in which case nitrous acid and ethyne must be used as flame gases. As silicates are present in colloidal form, the sample must be introduced into the AAS equipment using an ultrasonic nebulizer. Such a nebulizer is also used when silicate is measured by ICP-AES.

*Analysis of bromate in raw and drinking water* In the recent past the analysis of bromate in water has received considerable attention. Not only ozone, but also other strong oxidizing components are applied for the preparation of safe drinking water. By the application of these substances bromate ion may be formed during ozonization of bromide-containing compounds in the waters. Bromate is determined in raw and drinking water with IC. Specific conductimetric detection is combined with the determination of bromate by IC with a concentration of bromide. The most important step is the unselective enrichment of all water constituents by means of a rotator evaporator and a selective removal of bromate in raw and drinking waters is possible reduce to concentrations of at least  $1 \mu\text{g l}^{-1}$ .

In the analysis of raw and drinking water components are of interest that are formed during the chlorination with for instance hypochlorite or chlorine dioxide and are physiologically active. Such components are amongst other bromate- and iodine-containing substances. After concentration of the sample bromate is determined with IC. The limit of the bromate determination is  $1 \mu\text{g l}^{-1}$ .

*Analysis of iodine in drinking water* The determination of iodine concentrations in drinking water is important to evaluate the occurrence iodine deficiency in humans. Iodine deficiency disorders are one of the world's most significant causes of mental retardation

and preventable brain damage. The lowest iodine level for drinking water has been reported to be  $5 \mu\text{g l}^{-1}$  by the World Health Organization (WHO).

For the determination of substances containing iodine, a portion of 10 ml of drinking water is transferred to a 25 ml calibrated flask. About 1.0 ml of  $0.5 \text{ mol l}^{-1} \text{ H}_2\text{SO}_4$ , two drops of bromine water, two drops of 10% (v/v) phenol, 0.5 ml of 0.5% (w/v) KI, and 1.0 ml of 1% (v/v) starch solution is added. The solution filled up to the mark with distilled water and mixed. After 10 min, the absorbance of the solution is measured spectrophotometrically at 590.0 nm against a reagent blank.

**Microcomponents** Inorganic microcomponents cover almost the entire periodic table. Here we discuss only those elements that are determined most frequently: beryllium, vanadium, chromium, cobalt, nickel, copper, zinc, arsenic, selenium, silver, cadmium, antimony, barium, and lead. The techniques of choice are FAAS, graphite furnace-AAS (GF-AAS), ICP, and hydride generation-AAS (HG-AAS). An ultrasonic nebulizer has recently become commercially available for FAAS and ICP-AES, which decreases the lower determination limits. ICP-mass spectrometry (ICP-MS) is a recent development in which ionization is combined with sensitive mass discrimination. In a further development a graphite furnace is used in front of the ICP-MS. Selective evaporation of elements in the graphite furnace reduces the influence of highly interfering matrices. ICP-MS is expensive, which deters its widespread use.

Arsenic, selenium, and antimony can be measured at low concentrations with HG-AAS. Digestion with aqua regia in a microwave oven is necessary prior to the determination. Next, hydroxylammonium chloride is added as a neutral solution; iodide may be added to accelerate the reaction. For arsenic or antimony a reducing agent such as ascorbic acid has to be added to convert all arsenic or antimony to a single oxidation state. A background correction is required; for this purpose apparatus with a deuterium lamp corrector can be used but Zeeman background correction is preferred.

Determination is also possible with GF-AAS. However, this method has a higher limit of detection and suffers interference from many substances.

Currently, the remaining elements listed above are usually determined with GF-AAS equipped with deuterium or preferably Zeeman correction. Matrix modifiers such as  $\text{Mg}(\text{NO}_3)_2$ ,  $\text{Pd}(\text{NO}_3)_2$ ,  $\text{La}(\text{NO}_3)_3$ ,  $(\text{NH}_4)_2\text{HPO}_4$ , or  $(\text{NH}_4)_2\text{SO}_4$  are required. A limit of detection of  $1 \mu\text{g l}^{-1}$  can be realized. Over the largest part of the working range a precision of 5–10% is attainable and there is a range of about two decades between the uppermost and lowest limits of determination. To obtain unambiguous absorption in AAS, the elements have to be in the same oxidation state and therefore a reducing agent is added. Triton X-100 is added to prevent adsorption effects in the AAS itself. Some characteristics of AS methods are summarized in Tables 1–3. In Table 2, the limits of determination for the inorganic microcomponents mentioned above are given for real samples. These limits are up to 2–10 times higher than the limits that are generally specified, which are determined from standard solutions without interferences.

**Table 2** Limits of determination in real samples

Element	Limit of determination ( $\mu\text{g l}^{-1}$ )		
	FAAS	GF-AAS	HG-AAS
Ag		1	
As		1	0.2
Ba		5	
Be		0.05	
Cd		0.1	
Co		1	
Cr		0.5	
Cu		1	
Ni		1	
Pb		0.5	
Sb		1	0.5
Se		1	0.2
V		1	
Zn	5	1	

Limit of determination is the minimum level that can be reliably achieved by a method within specified limits of precision and accuracy.

**Table 1** Characteristics of atomic spectrometric methods

Method	Repeatability (%)	Limit of detection (g)	Sample volume (ml)	Time (min)	Simultaneous analysis
FAAS	2–5	$10^{-6}$ – $10^{-7}$	10–100	6	No
GF-AAS	8–12	$10^{-11}$ – $10^{-12}$	0.1–2	6	No
HG-AAS	5–10	$10^{-8}$ – $10^{-9}$	100	6	No
ICP-AES	5–20	$10^{-5}$ – $10^{-6}$	10–100	6	Yes

Limit of detection is the lowest concentration of an analyte that can be detected at a specific confidence level.

**Table 3** Matrix modifiers for atomic absorption spectrometric determination of some elements, with some figures of merit

Element	Interferents	Matrix modifier	Limit of determination ( $\mu\text{g l}^{-1}$ )	Repeatability (%)
Ag	Various	$(\text{NH}_4)_2\text{HPO}_3$	1	5–10
Ba	Various	$\text{La}(\text{NO}_3)_3$ , $\text{Mg}(\text{NO}_3)_2$	5	5–10
Be	Al, Ca	$\text{La}(\text{NO}_3)_3$	0.05	5–10
Cd	Cl, Sb	$\text{Pd}(\text{NO}_3)_2$ , $\text{Mg}(\text{NO}_3)_2$ , Triton X-100, reductor	0.1	5–10
	Zn, organics	$(\text{NH}_4)_2\text{SO}_4$	0.1	5–10
Co	Volatile with Cl, P, S	$\text{Mg}(\text{NO}_3)_2$	1	5–10
Cr	Desorption	$\text{Pd}(\text{NO}_3)_2$ , reductor, Triton X-100	0.5	5–10
	$\text{Cr}^{3+}/\text{Cr}(\text{VI})$	$\text{Mg}(\text{NO}_3)_2$	0.5	5–15
Cu	Cl, $\text{Cu}_2\text{O}$ , Fe	$\text{Pd}(\text{NO}_3)_2$	1	5–10
Ni	Cr	$\text{Mg}(\text{NO}_3)_2$	1	5–10
		$\text{Pd}(\text{NO}_3)_2$ , reductor, Triton X-100	1	5–10
Pb	Cl	$(\text{NH}_4)_2\text{HPO}_4$	1	5–10
Zn		—	5	5–10
V	Formation of various carbides	$\text{Mg}(\text{NO}_3)_2$	1	5–10

*Monitoring trace elements in waters by ICP-AES*

How to avoid spectroscopic interferences is an important issue during the development of any analytical method. Such interference is also important in the application of ICP-EAS. Elements commonly present in environmental samples give rise to difficulties in the determination of other elements at ultratrace concentrations. For simplicity a list of alternative emission lines based on relative differences between intensities of the measured elements and their interferences are omitted in **Table 4**.

*Monitoring trace elements in waters by ICP-MS*

A simple, rapid, and accurate panoramic method based on ICP-MS has been developed for the determination of ultratrace concentrations of metals in water samples. On the basis of an appropriate selection of the isotopes monitored and combination of internal standardization with correction equations to overcome the matrix effects, the method permits accurate determination of up to 60 elements in a single run of less than 3 min.

Assignments of intensities and calculation of concentrations can be performed by general element survey and specified software. Precision (RSD) below 5% is commonly achieved for elements present at  $25 \mu\text{g l}^{-1}$ . To correct for matrix-induced ion signal variation and instrumental drift, rhodium or indium in combination with panoramic analysis, based on full mass-spectra scan methods, is used as the internal standard (IS). Spectroscopic effects due to Cl, Na, Ca, Mg, S, and C were corrected with interference factors (IF) on the basis of a set of correction equations (see **Table 5**).

Hence, it is less suited for a fast panoramic analysis. In this list the interference factors associated to

the polyatomic species containing one isotope of the previously mentioned interference elements (Cl, Na, Ca, Mg, S, P, and C) in combination with argon, nitrogen, oxygen, or hydrogen demonstrate the daily determination of the interference factors and provide the possibility of increasing the sample throughput considerably.

*Mercury in water by ICP-MS* ICP-MS with addition of gold allows the previously difficult measurement of low concentration of mercury in water.

*Multicollector-ICP-MS* Using MC-ICP-MS offers the possibility of isotope ratios. The development of multicollector ICP systems allows studies of previously immeasurable nonstable transition metals ( $^{13}\text{C}/^{12}\text{C}$  and  $^{16}\text{O}/^{18}\text{O}$ ) isotope ratios.

*Early warning detection and monitoring* A sensor is a device that gives information about the presence or absence of a component of interest. The advantage of sensors is that the sensor measures continuously with the same device. Therefore, the measurements are reliable. This is essential for determinations in the domain of medicinal, chemical, and production industries. Sensors are cost-effective and innovative for analysis of water at point locations.

A new concept sensor is used for the analysis of range 7 compounds in water. The module provides outputs for pH, dissolved oxygen, chlorine, temperature, conductivity, and redox potential, suiting a wide range of applications from laboratory measurements to environmental monitoring. Next, a hybrid sensor is being developed that combines the sensitivity of piezoelectric nanobalance technology with the selectivity of stripping potentiometric analysis for the

**Table 4** Summary of analyte emission lines for ICP-AES measurements used to eliminate interferences

<i>Wavelength (nm)</i>	<i>Rel. intensity</i>	<i>Signal/noise</i>	<i>BEC</i>	<i>Interferences</i>

volatile organic compounds (e.g., toluene) in the parts per million concentration range. The prototype devices had fast response times, low detection limits, highly reversible behavior, and excellent stability.

### Organic Chemical Analysis

There are many more organic compounds present in water than there are inorganics. Their chemical and physical properties are often very closely related,

which makes it very difficult to discriminate a single compound from others that are also present in the sample. Generally, a method of analysis includes the following steps:

1. Isolation from the water, which usually also includes a preconcentration step.
2. Separation from interfering compounds that are isolated from the water together with the determinant (cleanup).
3. Further concentration in order to enable detection of the compound.
4. Instrumental chromatographic separation and detection.

These steps in the analysis are described below.

The selection of an isolation and/or concentration technique and the instrument for the measurement depends largely on the class of compounds that are to be analyzed. Sometimes it is necessary to analyze simultaneously a wide variety of chemical compounds in the sample. Application of a series of techniques can provide the solution.

For organic residue analysis of samples, several isolation, concentration, cleanup, and detection techniques are available, e.g., liquid-liquid extraction (LLE), use of a sorbent, and headspace analysis (HSA). Purge-and-trap and/or closed-loop stripping analyses (CLSAs) may be used for highly volatile compounds (e.g., chloroform). Often a concentration step is necessary in the procedure in order to reach the concentration range that can be detected by an instrumental technique. It may be necessary to change the chemical nature of the compound to be analyzed by derivatization in order to make it possible to separate the compound from the matrix or to discriminate it from other interfering compounds or to improve the detection.

Instrumental techniques that are most commonly used are gas chromatography (GC) and liquid chromatography (LC), both in combination with a wide range of detectors. With instrumental chromatographic techniques it is possible to make further discrimination between organic compounds before detection. The choice of the column in GC and LC is very important and the detector can be very specific. It is important to set up an optimal combination of steps in the analytical procedure.

The procedure in an analytical scheme for the analysis of a wide range of organic compounds may be a combination of a gas-stripping technique for the volatiles and a number of adsorption or extraction steps. Alternatively, the sample can be passed through an adsorbent resin. The organics that pass the resin can be isolated from the effluent by means

of freeze-drying concentration. An isolation-fractionation scheme can be set up in which organic compounds with different functional groups and sorption parameters are separated and concentrated in fractions with similar behavior, which permits instrumental analysis. However, in practice there are several organic classes that still cannot be efficiently recovered.

**Direct aqueous injection** Direct injection of a sample without any sample treatment into an instrument such as a gas chromatograph or high-performance liquid chromatograph is the simplest and fastest analytical procedure for the analysis of organic pollutants in surface water. However, most columns are not water resistant: support surfaces or stationary phases hydrolyze. Resistant column types are polyglycols, e.g., carbowaxes on a barium carbonate surface. Water is also very strongly retained and inert columns with immobilized silicone coatings (apolar) that have almost no retention for water must be used. However, columns can be deactivated in such a way that direct water injection is possible. The influence of water on a GC detector can be such that the flame ionization detector (FID) flame will be extinguished immediately after the injection or the electron-capture detector (ECD) ground current will effectively be quenched.

On-column injection produces no problems with strongly water-soluble (fully trapped) solutes, few or negligible problems with water-insoluble solutes (non-trapped), and some problems with solutes of intermediate solubility (partially trapped). Splitless GC injection can only be used for strongly soluble solutes.

A very thick film (1–8  $\mu\text{m}$ ) with a high loading capacity can be useful for direct injection. For direct determination of organic compounds in water, a gas chromatographic/concentration apparatus can be used in which organic compounds are retained on a collection precolumn. After venting the water (10–200  $\mu\text{l}$ ) the precolumn is heated rapidly (a few seconds). The method is especially useful for compounds that are difficult to extract or to purge from water. The apparatus can be used in combination with GC-FID, ECD, nitrogen/phosphorus-alkali FID, and photoionization detectors.

Trace substances can be adsorbed from the sample onto a bonded hydrophobic-phase capillary column when it passes through the capillary column at room temperature. These substances are subsequently thermally desorbed, trapped, and analyzed by GC using either the same column or one in series. Utilizing a single column with FID, concentrations can be determined at the microgram per liter level,

while using two columns with ECD allows concentrations to be determined at the nanogram per liter level. A Tenax-GC column in combination with FID for the analysis of organic compounds (e.g., alcohols, acetates, ketones, ethers) gives good results.

In another simple method of direct aqueous injection GC, water is selectively removed by diffusion across a permselective membrane prior to the sample entering the GC column. Injection volumes are 1–20  $\mu\text{l}$ .

Steam can be used as the carrier gas in GC. The sensitivity is  $10\mu\text{g l}^{-1}$  for hydrocarbons. The FID gives a constant and reproducible response, which, however, is lower than under conventional GC conditions.

It is almost always important to avoid direct contact of the water with the GC column. The direct aqueous injection technique is a simple and useful method for determination at relatively high concentrations.

**Xeno-estrogens** It is supposed that the degradation products of penicillin, detergents (polyoxyethylenes), and softening agents have hormonal residual activity in surface water that is adverse for water organisms. At present such emerging substances are measured with liquid chromatography (LC) coupled with MS-MS (LC-MS-MS). The advantages of the LC-MS-MS method is the extended linear range and superior sensitivity, providing a limit of quantification of 0.1 to  $10\text{ ng ml}^{-1}$  for previously difficult monitoring of biofluids and metal-containing compounds in biological matrices. Large-volume injection-LC-ESI-MS-MS in positive or negative ion mode enables the detection of, respectively, negative ion compounds, such as nitrofurantoin, clofibrine acid, bezafibrate, and ibuprofen, and positive compounds such as amoxicillin, ciprofloxacin, cephalixin, metoprolol, paracetamol, sulfamethoxazole, erythromycin, ifosfamide, carbamazepin, and fenofibrate.

### Isolation and preconcentration

**Liquid-liquid extraction** LLE is a simple conventional technique for isolation and concentration. Which classes of compounds can be extracted from samples depends on a number of factors, such as type of sample (presence of particulate matter, ionic strength of the water), pH, type of extraction solvent (polarity of the solvent is the main factor), solvent-to-water ratio, and extraction procedure. Extraction at approximately pH 7 can be inefficient for some classes of compounds, e.g., phenols, which means that in such cases the sample pH has to be adjusted before extraction or consecutive extractions at

different pH values may be advisable. A low solvent-to-water ratio can lead to the formation of an emulsion, and extraction may take a long time because of the slow kinetics involved in reaching equilibrium, especially for high-molecular-mass organic compounds. For extraction, a suitable immiscible solvent has to be used. If there is a high solvent-to-water ratio, a concentration step is usually necessary in order to improve sensitivity. Considerable loss of the more volatile compounds may occur if the extract is concentrated by evaporation. Concentration of the extraction solvent subsequently requires the availability of very pure solvents.

Some LLE techniques that have been in use for sometime are described below.

**Batch LLE (BLLE)** This technique involves shaking or stirring the sample with a small volume of solvent in an extraction vessel. Extraction of a sample with a very low volume of solvent is possible in a vessel with a narrow neck.

**Flow under continuous LLE** In this method, organics are extracted by bringing the sample and solvent into contact without breaking the interface between the two phases. Stirring of the aqueous layer prevents the process from being diffusion-limited. Distillation enables recycling of fresh solvent to extract the sample.

**Continuous LLE** An automated continuous LLE apparatus, based on the mixer-settler principle, can be constructed for use in the field. The apparatus consists of two extractors in series for serial extraction and can be applied at different depths. The units are loaded with  $\sim 200\text{ ml}$  of solvent and have the capacity to extract some  $100\text{ l}$  of water, depending on the solvent used.

Another apparatus for continuous extraction consists of three inverted  $250\text{ ml}$  volumetric flasks. A vibratory mixer is used for vigorous shaking of all three flasks. A  $10\text{ l}$  sample can be siphoned through the apparatus in  $\sim 4\text{ h}$  and extracted, with a total solvent volume of  $10\text{ ml}$ . The advantage is that no concentration step is involved.

Simple batch extraction is most widely used. The extraction efficiencies for semivolatile organic pollutants decrease in the order: pentane  $\geq$  hexane  $>$  hexane saturated with methanol  $>$  isooctane  $>$  15% (v/v) acetone in hexane  $\geq$  benzene. Pentane and hexane show the least interference with standard peaks during GC. Hexane is a more attractive extraction solvent than pentane because the volatility of pentane makes it difficult to handle, particularly when it is used with an automatic injector. The single-step

LLE procedure has some limitations when applied to samples containing large numbers of compounds. Analytical results for such samples are likely to be semiquantitative and will require careful evaluation. The hexane extraction procedure is, however, very useful as a simple, rapid screening method that can be applied to complement other methods. A low solvent-to-water ratio will give problems in the analysis of more foaming samples such as discharge water and the amount of solvent has to be increased. The use of large volumes of organic solvents and the high concentration factor of 100–10 000 subsequently requires solvents of very high purity. Concentration by evaporation gives a loss of volatile compounds and is laborious. A relatively new development is the technique using supercritical fluid carbon dioxide.

*Concentration of the extracts* Common solvent evaporation techniques that are acceptable for use in pollutant analysis include the following:

1. Kuderna–Danish evaporative concentrator equipment with a Snyder or Vigreux column for macro- and microanalysis, depending on the scale of the construction.
2. Rotary evaporation, equipped with a bump trap, under vacuum at ambient temperature. Application is restricted to macroanalysis.
3. Evaporation on a hot plate in an Erlenmeyer flask with or without a modified Snyder column, in which the solution is heated at 30°C. Macro and microanalysis.
4. Heated nitrogen blowdown in an Erlenmeyer flask, in which the solution is heated at 30°C with a gentle stream of nitrogen.

The recoveries improve markedly with the experience of the analyst. Nitrogen blowdown with column is significantly improved using dichloromethane as the solvent.

*Sorbent extraction* Sorbent extraction makes use of the differential distribution of the dissolved compounds between the solid sorbent and water. The use of organic porous polymers is advantageous for the extraction of organic compounds from water because: (1) the partition coefficients of compounds in a polymer–water system reach infinity if the correct polymer is selected for the types of contaminants present; (2) adsorption of water itself on the polymer is minimal; (3) the wettability of the polymer with water makes possible satisfactory transport of the substance toward the polymer surface; and (4) the polymer is inert.

Usually the sample is pumped through a column packed with a sorbent. The adsorbed compounds are then desorbed from the sorbent and analyzed chromatographically. The presence of mineral oil in the water at milligrams per liter levels considerably decreases the adsorption of compounds on the sorbent. This problem can be solved by using an extra layer of inert material at the entrance to the column. When water-containing organic compounds are passed through the column, a chromatographic process occurs and, after a certain time, breakthrough occurs. Under ideal conditions the trapping of organic compounds is 100%. This depends on a number of factors: sorbent, structure of the determinands, composition of the sample, and original concentration of the determinands in the water. Adsorption theory is very complicated, especially when water matrix effects are involved. Water characteristics may vary widely, and recovery studies are difficult to carry out. The water content of particulate matter and the way the organics are stuck to the particles are important. The nature of the active sites determines the ability of the organics to be extracted. When the water is first filtered, colloidal and small particles will pass through the filter and bring part of the organics through the extraction column more or less unaffected. When the water is not filtered, the adsorbent columns are easily clogged, resulting in channeling. Even pores may sometimes be blocked. The necessity to obtain resins of high purity and optimal adsorption capacity is a problem. An extended cleanup procedure for trace analysis is mandatory; this procedure can be automated.

Desorption of the compounds from the sorbent can be performed either with a liquid or by heating. Solvents used include diethyl ether, n-hexane, acetone, isopropanol, methanol, methylisobutyl ketone, and pyridine. The solvent strength is also important; for example, in a stream containing activated carbon the solvent strength increases as follows: water < methanol < ethanol < acetone < propanol < diethylether < butanol < ethyl acetate < n-hexane < benzene. Sometimes the desorbed compounds are led directly into the chromatographic column for LC. In thermal desorption, the column is situated before the analytical column of the GC, similar to HSA. In order to eliminate peak broadening, the initial sections of the chromatographic columns are usually cooled. The temperature must be such that all compounds contained in the sorbent are transferred from it to the GC in a reasonable amount of time. If the temperature is too high, the substances can decompose.

Classes of compounds that can be extracted with the various absorbents include:

XAD-2: PCBs, phthalates, carbamates, alkylbenzenes;  
 XAD-4: Chloroethers, acids, phenols, humic acids;  
 XAD-7: Amino acids, PAHs;  
 Active carbon hydrocarbons: phenols, PAHs;  
 Chromosorb 102: Chlorobenzenes;  
 Tenax-GC: PAHs, chlorobenzenes; and  
 Sep-pack: PAHs, phenols, PCBs, aliphatic carboxylic acids.

A wide range of organic compounds can be extracted using different resins; however, good extraction of highly volatile compounds with a resin is not possible.

**Liquid chromatography** Another possibility is the use of online trace enrichment in LC using a precolumn. The method consists of an online preconcentration step and a postcolumn reaction step. Online preconcentration of mono- and dichlorophenols from aqueous samples has been performed using PRP, a diphenylbenzene–styrene copolymeric sorbent, as packing material for both analytical column and precolumn. Enrichment factors of over 300 can be obtained. The method is suitable for the analysis of effluent samples. A precolumn, when used for preconcentration, serves for sample cleanup and as a guard column at the same time. A guard column protects the valuable analytical LC column against contamination by sample, mobile-phase constituents, and grit released by the chromatographic equipment, including the injector. The requirements that have to be met by a precolumn are summarized as follows:

1. The amount of material should be sufficient for the preconcentration of the desired amount of determinand from a given volume of sample.
2. The precolumn has to be as small as necessary to prevent peak broadening and must have a high-pressure capability. It should not present back-pressure limitations during sampling at high flow rates; it should be easily replaceable and easy to repack, and should be compatible with all eluents generally used in LC.
3. Field sampling and automated sampling handling must be feasible.

Preconcentrations have been performed on both C18 and carbonaceous sorbents.

**Headspace analysis** By analyzing the gas phase that is in equilibrium with the water phase, instead of the water phase, it is possible to eliminate many drawbacks present in the usual methods of

preconcentration (e.g., LLE). Determination of trace organic volatiles in the gas phase above the sample is known as HSA. The techniques of HSA can be divided into two groups, static and dynamic.

**Static headspace analysis** The sample for chromatographic analysis is taken from a closed vessel where the material under study reaches equilibrium with its vapor at a predetermined temperature. Experimental conditions that can influence the results are the temperature and the sample-withdrawal technique. The concentration of the analytes in the gaseous phase can be increased by raising the temperature, adding an electrolyte, and varying the pH. Solutes with low vapor pressures cannot be detected.

**Dynamic headspace analysis** A stream of inert gas (helium or nitrogen) strips the volatile compounds, e.g., organohalogen hydrocarbons, from the water and passes them through a sorbent or cryogenic trap or through a combination of the two. The volatiles are eluted from the sorbent with a solvent or are thermally desorbed and brought into the gas chromatograph or other instrument. Often these techniques are online. The technique can be applied in an open system, where the stripping gas is vented to the atmosphere, or in a closed circuit, where the gas phase is recycled through the water and trap, closed loop sample analysis (CLSA). Internal and external standards can be used to improve reproducibility. Multiple headspace extraction (MHE) can be applied, which is based on a stepwise gas extraction with intermediate HSA. A simple two-step procedure is adequate for practical applications. The optimum static HSA sampling conditions are pH 7.1, 50°C, and  $3.35 \text{ mol l}^{-1}$  sodium sulfate for adjusting ionic strength.

**Purge and trap techniques** With dynamic procedures, the volatile compounds can be enriched to reach the detection limit of the chromatographic system. The trap packed with a solid sorbent can be considered as a chromatographic column. When the volume of the inert purge gas through the column becomes equal to the retention volume of the determinand (at a given temperature), it breaks through and elutes from the column. Knowledge of these breakthrough volumes is necessary. The breakthrough value depends on the form and size of the trap tube, specific area, and particle size of adsorbent, temperature, flow rate of the stripping gas, original concentration of the determinand in the sample, chemical structure of the determinand, and the purge gas. Elution of the volatiles from the trap is performed with small volumes of organic solvents such as methanol, isopropanol, or acetone.

Often, to increase the concentration to reach the detection limit it is necessary to concentrate the eluate by evaporation. Drawbacks of solvent elution are the introduction of artifacts by the solvent, glassware, and gas; the peak in the chromatogram due to the solvent washing the volatile organic compounds; and loss of volatiles by evaporation. Desorption of the volatiles from the sorbent of the trap can also be carried out thermally, in which case the sorbent must have thermal stability and there must be no reactions of the volatiles with the sorbent. For thermal desorption, more complicated equipment is necessary than for elution with a solvent. A suitable choice of sorbent is essential for a successful result. A great number of sorbents are used, such as activated carbon, graphitized carbon black, and porous polymers that exhibit a characteristic low capacity for water and do not show irreversible adsorption or decomposition phenomena, e.g., Porapak, Chromosorb, Amberlite XAD resins, Tenax-GC, Spheron, Synachrom, and Cehachrom. Tenax-GC is widely used owing to its thermal stability, in spite of its lower specific surface area. Compounds determined with purge-and-trap techniques include halomethanes, chlorobenzenes, ethylbenzene, xylenes, and short-chain halogenated hydrocarbons.

**Closed loop sampler** Another type of dynamic HSA is the technique in which a stream of inert gas is passed over the sample and led through a trap. This method is similar to the purge-and-trap method. However, the equilibrium between the water and gas phases depends on the flow of the stripping gas. The surface contact is much smaller than in the purge technique. This technique can be applied to samples with considerable foaming. Stripping gas (0.5 l) is recycled continuously through the sample. The adsorption trap (1.5 mg of activated carbon) is extracted with 10  $\mu$ l of carbon disulfide. The range of compounds that can be measured is somewhat limited. Peaks of highly volatile compounds are hidden by the peak of the extraction solvent and moderately or extremely polar organic series are either poorly purged or not recovered at all. The CLSA technique has been used most often for screening of large numbers of compounds; its outstanding concentration factor without the need for an evaporation step makes the system useful even when only a few compounds are of interest.

The static headspace procedure is the simplest and can be applied to organic compounds with high vapor pressure and low solubility in water. Only simple equipment is necessary and there are no great problems with impurities. However, the method is relatively insensitive because only a part of the vapor

can be injected and there is no enrichment procedure. Sensitivity can be improved by optimizing the conditions and the method can be automated. MHE has higher sensitivity than the static method and compounds with lower vapor pressure can be determined, but special equipment is necessary. The method can be automated. MHE is frequently used in drinking-water analysis for the determination of trihalomethanes. With CLSA, it is possible to determine the widest scope of compounds. However, this technique has some practical problems such as contamination of the filter or system. Another possibility is thermal desorption, which is also semiautomated, but special equipment is necessary for the analysis.

**Steam distillation** A Bleidner apparatus can be used for the extraction of aromatic amines. In this system, a continuous steam distillation or continuous LLE is carried out and good recoveries are obtained (over 90%). The extraction solvent is isooctane and the extraction time is 2–3 h; the technique is not laborious. Steam distillation extraction can be used quantitatively for different types of organic substances at microgram per liter to nanogram per liter levels. Good results can be obtained within 20 min. Steam distillation results in a 'cleaner' extract and reduces the build-up of residue at the GC column. The small volumes of solvent normally used in steam distillation techniques facilitate solvent concentration and minimize interferences due to solvent impurities.

Various commercial extractors are available. The steam codistillation extractor allows simultaneous condensation of a steam distillate and an immiscible extraction solvent, e.g., dichloromethane. The steam distillator extractor passes a sample steam distillate through an immiscible lighter-than-water solvent such as hexane.

**Cleanup** The concentration and/or isolation technique applied has a great influence on the cleanup procedure. HSA techniques such as static headspace and purge-and-trap with thermal desorption have the advantage that no further cleanup is necessary. These techniques are restricted to the analysis of volatile compounds. A high selectivity of the concentration and/or isolation technique decreases the necessity of a further cleanup procedure. By a proper selection of the extraction solvent or the sorbent, the determinands can be extracted and separated simultaneously from the majority of coextractives. Also, a derivatization procedure can increase the selectivity of the method. The following procedures can be used for cleanup.

**Liquid-liquid partitioning** Liquid-liquid partitioning between two immiscible phases will separate

compounds of different solubilities. Thus, if the extract is a nonpolar solvent such as petroleum ether, it is partitioned with a polar solvent such as acetonitrile.

**Liquid-solid chromatography** Liquid-solid chromatography is the technique most widely used to clean up sample extracts. Silica gel, alumina, and Fluorisil are the most commonly used adsorbents. The adsorbent should be free of organic contaminants, inert to the determinands, effective in removing interferences, and uniform in activity from batch to batch. Column chromatography can also be used for preliminary fractionation of sample extracts, e.g., separation of PCBs from organochlorine compounds.

**Gel permeation chromatography** Gel permeation chromatography (size-exclusion chromatography) can be used on humic acids or fulvic acids in water and is frequently applied to the analysis of fatty samples such as fish. Gel permeation chromatography is a very effective method based on differences in molecular mass. Large molecules are excluded from the pores of the gels and are eluted first. This technique can easily be automated. However, after gel permeation chromatography for fractionation, additional liquid-solid column chromatography is still necessary. Thus, there is little advantage in using gel permeation chromatography for the cleanup of less fatty or nonfatty samples such as water.

**Liquid chromatography** LC can be used as a cleanup technique. One of the biggest advantages of LC is the possibility of automation. However, LC analytical columns can be deactivated by sample coextractives and regeneration of the columns is time consuming. A solution is to use small precolumns in series with the analytical column; this minimizes the effect. Good results are obtained for chlorophenols and other aromatics.

**Derivatization** Chemical derivatizations can have advantages such as increase in volatility, thermal stability, sensitivity, greater selectivity, and improvement of peakshape and/or separation behavior. There are several types of derivatization techniques, which are as follows:

1. Chemical derivatization as a prerequisite for the method of analysis, e.g., acylation of chlorophenols: It must meet all requirements associated with a practical, usable analytical method, such as reproducibility, good recovery, no interferences.
2. Chemical derivatization confirmatory test: The demands are less severe since the main criteria are speed, size of operation, and acceptable yield.

3. Cleanup reaction: Chemical reactions to clean up or remove specific interferences.

Examples of applications of derivatization reagents include: diazomethane for acids and phenols; acetic anhydride for phenols; heptafluorobutyric acid for anilines and phenols.

Derivatization can be carried out before instrumental analysis, or is often an integral part of the instrumental analysis such as oncolumn derivatization (GC); precolumn derivatization (LC); postcolumn derivatization (LC).

The lack of suitable detectors in LC for trace and ultratrace analysis of complex matrices has catalyzed this trend. The major advantage of postcolumn reaction detectors is the absence of artifact information, and the only requirement is good reproducibility. A disadvantage is the great influence of the mobile phase on the reaction medium.

Chemical reactions for cleanup are especially interesting in the analysis of organic compounds at very low concentrations in samples contaminated with many interfering compounds. One of the remarkable features of reaction detectors is their ability to fit into automated analytical systems. Their selectivity and sensitivity in the reaction itself will often permit a drastic reduction in the amount of sample preparation or the requirements for a powerful separation. Band broadening and interference of the detection signal with the reagent can be a problem.

**Chromatographic separation and detection** A wide range of analytical detection techniques are available for the determination of organic pollutants. GC is used on a large scale in the analysis of organic pollutants in samples. Capillary columns, selective detectors, and sample introductory techniques are widely used. Detectors for GC are summarized in **Table 6**. With the availability of low-inner-volume detectors, sophisticated sample introduction techniques, high quality of the capillary columns, multidimensional GC, derivatizing reagents, and multidetection systems, very highly efficient and sensitive systems are available for the analysis of trace organic pollutants in samples. The selection of the right chromatographic column and of the instrumental parameters is very important to get the optimal analytical tool. For the choice of a GC column, one should try to separate the particular sample on a small number of standard columns using the following guidelines. Study the table of stationary phases in the catalogs of the column supplier. Select a polar stationary phase to separate polar compounds and an apolar stationary phase for apolar compounds. Use the polarity index. Establish the appropriate internal diameter.

**Table 6** Detectors for gas chromatography

<i>Detector</i>	<i>Elemental or compound information</i>	<i>Minimum detectable amount</i>	<i>Linear dynamic range</i>	<i>Remarks</i>
AASD (atomic absorption spectrometric)	Monofunctional Hg	$10^{-10}$ g Hg		Expensive
AFID (alkali flame ionization)	Nitrogen/phosphorus	$10^{-13}$ – $10^{-14}$ g N or S	$10^4$ – $10^5$	Destructive; can also be used for S, As, Sb, Sn, Pb, Cl, I, F, Br
Coulometric	Cl, Br, I	$2 \times 10^{-13}$ – $10^{-15}$ g P s <sup>-1</sup>		
ECD (electron-capture)	Electron affinity, Cl, Br, I, F, nitrocompounds, conjugated carbonyls	$10^{-9}$ g $10^{-14}$ – $10^{-12}$ g aldrin(s)	$10^7$ $10^4$	Difficult in operation Cleanup of samples important
FID (flame ionization)	All compounds	0.02 coulomb per gram carbon	$10^6$ – $10^7$	Destructive; universal detector
FPD (flame photometric)	P, S	$10^{-12}$ g P s <sup>-1</sup>	$10^4$ – $10^8$	Destructive; also halogens
FTIR (Fourier transform infrared)	Functional group information	$5 \times 10^{-12}$ – $10^{-10}$ g S s <sup>-1</sup> $10^{-9}$ g	$10$ – $10^3$	Moderately expensive; discrimination between isomers
HECD (Hall electrolytic conductivity)	N, S, halogens	$10^{-9}$ g	$10^4$	Destructive; difficult in operation
MS (mass spectrometric)	Elemental and/or molecular information	$10^{-12}$ – $10^{-9}$ g		Destructive; expensive; high specificity
Microwave-induced plasma	Elemental	$10^{-9}$ g		Destructive; expensive; problems with O, P and N
PID (photoionization)	Aromatic compounds	$10^{-12}$ g	$10^7$	High selectivity
TCD (thermal conductivity)		$10^{-7}$	$10^5$	Nonspecific

Choose the appropriate column length and determine the optimum film thickness. The use of chemically bonded columns has many advantages. Rearrangement of the stationary phase film is impossible because of the chemical bonding; therefore, the efficiency of the columns is prolonged. Contaminated columns may be washed with solvents to regain their original performance.

The main benefit of multiple detection is the simultaneous registration of specific and selective items by a single injection, markedly reducing the analysis time. Destructive detectors can be mounted directly on nondestructive ones. Multidimensional GC enhances selectivity. Interesting peak groups from a complex mixture, eluting from a first capillary or packed column, can be transferred to a second column of high selectivity, for example, for organochlorines and PCBs. Capillary GC–MS is routinely used in water analysis, whereas GC–Fourier transform infrared (FTIR) has fewer practical applications. Capillary GC–FTIR has developed into an online technique whereby spectral data can be obtained in a short period of time even for difficult samples. Both techniques have sensitivities compatible

with capillary columns. Generally, capillary columns with higher capacity columns are useful in GC–FTIR. Considerably more sample is necessary for GC–FTIR analysis than for GC–MS. To solve identification problems, use of GC–MS and GC–FTIR has advantages and decreases total analysis time. It is also possible to use a combination of MS and FTIR with a built-in combined MS/IR library search.

LC is used for the analysis for a wide range of compounds too involatile or too thermolabile for analysis by GC. The analytical application of LC depends to a great extent on the availability of detectors with high sensitivity and adequate selectivity. The latter requirement is generally much more important in LC than in GC. In GC analysis of water it is certain that compounds with a high molecular mass will not generate peaks in the chromatogram of determinands with a lower molecular mass. However, interference of high-molecular-mass material is an omnipresent problem in trace analysis with LC. Selectivity can be improved by selective extraction, matrix removal, high efficiency of separation (by the suitable choice of phase system or multicolumn operation), and by selective detection. Important factors

**Table 7** Detectors for liquid chromatography

<i>Detector</i>	<i>Elemental or compound information</i>	<i>Sensitivity (g ml<sup>-1</sup>)</i>	<i>Linear dynamic range</i>	<i>Remarks</i>
UV-visible absorbance	Aromatics	$2 \times 10^{-10}$	$10^5$	Many applications; identification by diode array spectra
Conductivity	Ions	$10^{-5}$	$10^4$	
Amperometric	Oxidizable and reducible compounds	$10^{-12}$	$10^6$	
Fluorescence	PAHs, phenols	$10^{-11}$	$10^3$	High selectivity
Infrared	Macromolecules	$10^{-6}$	$10^4$	High selectivity
Refractive index	Alkanes	$10^{-7}$	$10^4$	Universal

**Table 8** Costs of steps of analysis in routine procedures for determination of organic compounds

<i>Technique</i>	<i>Cost of analysis (US\$)<sup>a</sup></i>
Filtration of water sample	20
Extraction (liquid-liquid)	35
Extraction (sorbent)	35
Purge-and-trap	35
Cleanup with sorbent	55
Derivatization	85
Instrumental detection, e.g., GC	55
GC-MS confirmation of compounds in addition to normal method	105
GC-MS detection, unknown compounds	760
GC-MS screening, known compounds	300

<sup>a</sup>Base year for prices, 1992.

that can accomplish selective LC detection are UV wavelength, simultaneous multiwavelength (photo-diode array), fluorescence, electrochemistry, atomic spectrometry, electron capture, homogeneous post-column reaction, and postcolumn reaction with extraction. Detectors for LC are summarized in Table 7.

LC is a suitable technique for trace analysis of organic micropollutants. However, the separation power of common LC columns is insufficient for very complex mixtures. Online coupling of LC with MS will be an attractive tool for analysis of low-volatility organic compounds in samples. However, cleanup of the sample prior to LC-MS analysis will be very necessary. The sensitivity is less than that obtained by capillary GC-MS combinations and at present there is no universal LC-MS system for all types of compounds.

**Table 9** Total cost of routine analysis of groups of compounds

<i>Compounds</i>	<i>Steps in procedure</i>	<i>Cost of analysis (US\$)<sup>a</sup></i>
Anilines, chlorinated	Bleidner extraction derivatization, GC-ECD	215
Aromatics, volatile and chlorinated hydrocarbons	Purge-and-trap, thermal desorption, GC-FID	90
PAHs 6 of Borneff	Liquid-liquid extraction, cleanup with alumina, LC-UV/fluorescence	130
PAHs 16 of EPA	Liquid-liquid extraction, cleanup with alumina, LC-UV/fluorescence	150
PCBs and organochlorine pesticides	Liquid-liquid extraction, cleanup with alumina and silica, GC-ECD	140
Phenols, chlorinated	Liquid-liquid extraction, acetylation, GC-ECD	170
Phthalates	Liquid-liquid extraction, GC-FID	140
Solvents, e.g., benzene, toluene, xylenes, di- and trichloromethane	Liquid-liquid extraction, GC-FID/ECD	125
Water-soluble solvents, e.g., acetone, alcohols, methyl- and other acetates	Direct injection, GC-FID	175

<sup>a</sup>Base year for prices, 1992.

In order to give an idea of the costs of the steps in the analytical procedure, these costs are summarized in Table 8. As an example, Table 9 gives the total costs of the analysis of different groups of compounds.

## Emerging Techniques

Miniaturization is the most promising development in analytical chemistry. With miniaturized analyzers determinations can be performed when needed and at any location. To date, CZE, miniaturized to chips, has been developed, but only for the analysis of pharmaceutical substances. The field developments in water analysis have been limited to such multiprobe measurements as pH, temperature, and oxygen. The Hydrion 10 is the instrument on the market that has proven capable of performing a complete analysis of a water sample for the main constituents within a matter of minutes. The development of such devices will continue, with the expectation that apparatus for rapid analysis of samples in the field will be both easily available and more readily applicable in future. However, much of the present methods of analysis are time consuming and costly. Moreover, the results are not readily available. Therefore, direct intervention is not possible. This was passed when sensors became available. With sensors major ions can be measured in water in a manner that is fast, inexpensive, and independent of laboratory tests. Because the measurement results are directly available, it is possible to apply them immediately. Next in new developments are early warning detection and monitoring with biomonitors (*Daphnia*, algae, fish, etc.) that measure changes in the functions of organisms in response to pollutants will respond to several toxic compounds. This future activity could reshape new challenges to expand biological early warning systems and cytosensors for possible compounds such as atrazine, malathion, diuron, dieldrin, dioxins, estrogens, mutagens, aldrin, cadmium, etc.).

The monitoring of compounds with dedicated analytical methods is often insufficient to assess and maintain the quality of surface waters. Many unknown compounds can be present, some of them are harmful for the environment and also for humans. For the identification of semipolar and polar target compounds present in water, LC database fingerprints in combination with LC-MS/MS identification or LC database toxic fingerprint in combination with LC-MS/MS identification can improve the efficiency on relevant compounds.

## Potable Water

### Introduction

‘Water’ is one of the most abundant substances in the world. However, the conversion of water from various sources to good-quality drinking water can be a very demanding task for drinking water suppliers. The definition of drinking water commonly refers to water that is intended for human consumption and other domestic uses. Ideally, drinking water should be clear, colorless, and without unpalatable taste or odor. In addition, it must not contain harmful chemical substances, either organic or inorganic, and pathogenic microorganisms that may be harmful to human health.

The quality of drinking water in relation to public health is an important issue worldwide. Water may come from groundwater sources or surface waters such as lakes, reservoirs, and rivers with a wide variation in water quality. The treatment required to achieve potability depends upon the characteristics of the source, relevant drinking water standards, and the characteristics of the distribution system. Treatment of some supplies consists of disinfection only while others may use several clarification steps prior to disinfection.

*The Guidelines for Drinking-Water Quality* published by the World Health Organization (WHO) is the key international reference point for standard setting and drinking water safety. The WHO has developed a series of guidelines that present an assessment of the health risks associated with exposure to health hazards through water. The information is essential to assist water suppliers to implement their own safe water acts.

Drinking water suppliers must have a good quality assurance program to ensure that the product (drinking water) they supply to the consumer meets the relevant standards. Analysis of drinking water becomes an important step of the program. It is necessary to monitor key locations in the water supply system with the support of good analytical procedure and quality control to ensure the accuracy of the analysis.

### Drinking Water Guidelines and Standards

In 1984, the term ‘guidelines’ was first introduced by the WHO, which were intended to be used as a basis

for the development of national standards to ensure the safety of drinking water supplied to the consumer. Drinking water standards are regulations that water authorities set to control the level of contaminants in their drinking water. The advantage of using guidelines rather than the adoption of international standards for drinking water quality is the flexibility of the risk–benefit approach in the establishment of local standards and regulations. This could allow standards and regulations to be implemented with different priorities according to the local or national, environmental, social, economic, and cultural conditions. In developing standards, it is important to realize that the standards should be both practical and feasible to implement. They need to take into account the likelihood that the contaminant occurs in a public water system, the levels of concern, and the determination limits of the analytical methods. This can prevent the situation of unnecessary monitoring for relatively minor concern substances.

Chemicals, arising from natural or human activities, can enter the water supply and potentially contaminate the water. Inorganic chemicals such as mineral salts leached from mining sites, organic chemicals such as algal toxins as a result of an algal bloom, man-made chemicals such as pesticides (insecticides and herbicides), pharmaceuticals, and industrial waste products can enter the water supply. Some potentially hazardous chemicals in drinking water are derived directly from treatment chemicals, such as the unreacted monomer from polyelectrolytes used as coagulant aids, and disinfectant reactions with organic matter to form disinfection by-products. Lists of contaminants of concern in drinking water are shown in **Tables 1** and **2** for inorganic and organic contaminants, respectively.

Most water authorities have set standards for drinking water quality. Authorities who play a major role in developing drinking water standards are the United States Environmental Protection Agency (USEPA) and the European Economic Community (EEC). Other countries including Canada, Germany, United Kingdom, Netherlands, Czech Republic, South Africa, China, Taiwan, have also implemented standards to regulate the delivery of safe drinking water to the consumers. In Australia, the National Health and Medical Research Council (NHMRC) in conjunction with the Australian Water Resources Council (AWRC), and more recently with the Agricultural & Resource Management Council of Australia and New Zealand (ARMCANZ) have developed guidelines that are based on the WHO

**Table 1** Contaminant concentrations or values of physical characteristics for inorganic chemicals and radioactive substances in drinking water

	<i>Description and possible sources of contamination</i>	<i>Sam. Loc.</i>	<i>WHO drinking water guideline value</i>	<i>USEPA maximum contamination level (MCL)</i>	<i>USEPA recommended method</i>
Alpha particles (gross alpha activity)	Certain minerals are radioactive and may emit a form of radiation called alpha radiation	RW	0.1 Bq l <sup>-1</sup>	15 pCi l <sup>-1</sup>	Evaporation, co-precipitation
Aluminum	From natural sources and used as coagulant for water treatment	DS	0.2 mg l <sup>-1</sup> *	0.2–0.5 mg l <sup>-1</sup> *	ICP-AES, ICP-MS, AAS
Ammonia (as NH <sub>3</sub> )	Presence may indicate sewage contamination and/or microbial activity	DS	1.5 mg l <sup>-1</sup> *	No value set	ISE, colorimetric (indophenol)
Antimony	From natural sources or discharge from petroleum refineries, fire retardants, electronics, and solder	SC	0.005 mg l <sup>-1</sup> p	0.006 mg l <sup>-1</sup>	ICP-MS, AAS
Arsenic	From natural sources or discharge from mineral/industries/agricultural wastes	RW	0.01 mg l <sup>-1</sup> p	0.01 mg l <sup>-1</sup>	ICP-AES, ICP-MS, AAS
Asbestos	From dissolution of mineral/industrial waste and deterioration of cement water mains	DS	U	7 million fibers per liter	TEM
Barium	From natural sources or discharge from industries	RW	0.7 mg l <sup>-1</sup>	2 mg l <sup>-1</sup>	ICP-AES, ICP-MS
Beryllium	From natural sources or discharge from industries	RW	NAD	0.004 mg l <sup>-1</sup>	ICP-AES, ICP-MS, AAS
Beta-particles (gross beta activity)	Certain minerals are radioactive and may emit a form of radiation called beta-radiation	RW	1 Bq l <sup>-1</sup>	4 millirems per year	Evaporation, co-precipitation
Boron	From mineral leaching and may be associated with seawater intrusion	RW	0.5 mg l <sup>-1</sup> p	No value set	Colorimetric
Bromate	Possible by-product of disinfection using ozone	SC	25 µg l <sup>-1</sup> p	0.01 mg l <sup>-1</sup>	IC
Cadmium	Indicates industrial or agricultural contamination	SC	0.003 mg l <sup>-1</sup>	0.005 mg l <sup>-1</sup>	ICP-AES, ICP-MS, AAS
Chloramine (Monochloramine)	Disinfection agent	SC	3 mg l <sup>-1</sup>	4 mg l <sup>-1</sup> as Cl <sub>2</sub> (MRDL)	Amperometric titration, DPD iron(II) titration, DPD colorimetric
Chloride	From natural mineral salts. No health-based guideline value	TW	250 mg l <sup>-1</sup> *	250 mg l <sup>-1</sup> *	IC
Chlorine	Disinfection agent. Commonly analyzed using DPD (N,N-diethyl-p-phenylenediamine) colorimetric methods	SC	5 mg l <sup>-1</sup> , 0.6–1.0 mg l <sup>-1</sup> *	4 mg l <sup>-1</sup> (MRDL)	Amperometric titration, DPD iron(II) titration, DPD colorimetric
Chlorine dioxide	Disinfection agent	SC	NAD, 0.4 mg l <sup>-1</sup> *	0.8 mg l <sup>-1</sup> as ClO <sub>2</sub> (MRDL)	Amperometric titration, DPD methods
Chlorite	By-product of chlorine dioxide disinfectant	SC	200 µg l <sup>-1</sup> p	1 mg l <sup>-1</sup>	IC
Chromium (as Cr(VI))	Indicates industrial or agricultural contamination	DS	0.05 mg l <sup>-1</sup> p	0.1 mg l <sup>-1</sup>	ICP-AES, ICP-MS, AAS
Copper	Corrosion of copper pipes/fittings by soft, low pH water	SC	2 mg l <sup>-1</sup> p, 1 mg l <sup>-1</sup> *	1.3 mg l <sup>-1</sup> , 1 mg l <sup>-1</sup> *	ICP-AES, ICP-MS, AAS
Cyanide	From industrial waste and some plants and bacteria	DS	0.07 mg l <sup>-1</sup>	0.2 mg l <sup>-1</sup>	Colorimetric
Fluoride	Occurs naturally and water additive which promotes strong teeth	TW	1.5 mg l <sup>-1</sup>	4 mg l <sup>-1</sup> , 2 mg l <sup>-1</sup> *	IC
Hydrogen sulfide	Formed in water by sulfate-reducing microorganism	DS	0.05 mg l <sup>-1</sup> *	No value set	Colorimetric, iodometric, ISE
Iron	Occurs naturally. No health-based guideline value	SC	0.3 mg l <sup>-1</sup> *	0.3 mg l <sup>-1</sup> *	ICP, AAS
Lead	Dissolution from natural sources or household plumbing	SC	0.01 mg l <sup>-1</sup>	0.015 mg l <sup>-1</sup>	ICP-MS, AAS
Manganese	Occurs naturally. No health-based guideline value	DS	0.5 mg l <sup>-1</sup> p, 0.1 mg l <sup>-1</sup> *	0.05 mg l <sup>-1</sup> *	ICP-AES, ICP-MS, AAS

Mercury	From industrial emissions/spills	RW	0.001 mg l <sup>-1</sup>	0.002 mg l <sup>-1</sup>	Cold vapor AAS, ICP-MS
Nickel	From nickel-plated fittings	SC	0.02 mg l <sup>-1</sup>	0.1 mg l <sup>-1</sup>	ICP-AES, ICP-MS, AAS
Nitrate (as NO <sub>3</sub> <sup>-</sup> )	Occurs naturally	DS	50 mg l <sup>-1</sup>	10 mg l <sup>-1</sup>	IC, colorimetric
Nitrite (as NO <sub>2</sub> <sup>-</sup> )	Rapidly oxidized to nitrate	DS	3 mg l <sup>-1</sup> (acute), 0.2 mg l <sup>-1</sup> (chronic) <sup>p</sup>	1 mg l <sup>-1</sup>	IC, colorimetric
pH	<6.5 may cause corrosion, >8 decreases efficiency of chlorination	DS	<8.0*	6.5–8.5*	Electrometric
Radium-226	Radionuclide	RW	No value set	5 pCi l <sup>-1</sup>	Radiochemical, radon emanation
Selenium	Generally very low concentration	RW	0.01 mg l <sup>-1</sup>	0.05 mg l <sup>-1</sup>	ICP-MS, AAS
Silver	Silver and silver salts occasionally used for disinfection. No health-based guideline value	RW	U	0.1 mg l <sup>-1</sup> *	ICP-AES, ICP-MS, AAS
Sodium	Natural component of water. No health-based guideline value	TW	200 mg l <sup>-1</sup> *	No value set	ICP-AES
Sulfate	Natural component of water, may be added via treatment chemicals	TW	250 mg l <sup>-1</sup> *	250 mg l <sup>-1</sup> *	IC, colorimetric
Taste and odor	No health-based guideline value. The threshold odor number (TON) is the greatest dilution of sample with odor-free water yielding definitely perceptible odor	SC	No value set	3 TON*	Flavor profile analysis
Total dissolved solids (TDS)	<500 mg l <sup>-1</sup> is regarded as good-quality drinking water	TW	1000 mg l <sup>-1</sup> *	500 mg l <sup>-1</sup> *	TDS
True color	15 True color unit (TCU) just noticeable in a glass	DS	15 TCU*	15 TCU*	Visual comparison, spectrophotometric
Turbidity	Turbidity is a measure of the cloudiness of water. Nephelometric turbidity unit (NTU) 5 just noticeable in a glass	DS	5 NTU*	1 NTU	Nephelometric
Zinc	Corrosion of galvanized pipes/fittings and brasses	SC	3 mg l <sup>-1</sup> *	5 mg l <sup>-1</sup> *	ICP-AES, ICP-MS

Sam. Loc. (sample location): RW – raw water, TW – treated water, DS – distribution system, and SC – supply to consumer 'consumer taps'.

U: It is unnecessary to recommend a health-based value for these compounds because they are not hazardous to human health at concentrations normally found in drinking water.

NAD: No adequate data to permit recommendation of a health guideline value.

\*Aesthetic guideline value.

p: provisional guideline value.

USEPA MCL: the highest level of a contaminant that is allowed in drinking water.

MRDL: maximum residual disinfection level.

Analytical methods: AAS, atomic absorption spectroscopy; ICP-AES, inductively coupled plasma-atomic emission spectroscopy; ICP-MS, inductively coupled plasma-mass spectrometry; IC, ion chromatography; ISE, ion selective electrode; TEM, transmission electron microscopy.

Standard methods for the examination of water and wastewater (shaded portions): The detailed information of this table is obtained from WHO – *Guidelines for Drinking-Water Quality*, 2nd edn (1993), USEPA – *National Primary Drinking Water Standards* (1995), NHMRC/ARMCANZ – *Australian Drinking Water Guidelines* (1996), USEPA – *Methods and Guidance for Analysis of Water*, Version 2 (1999), and APHA – *Standard Methods for the Examination of Water and Wastewater*, 20th edn (1988). This table is produced to illustrate the contaminant of concerns and their concentrations in drinking water in relation to the analytical techniques used for the determination. For detailed analytical procedure, derivation of guideline/standard values, and health-related concern of contaminant level in drinking water consult the original publication cited and more preferable to obtain the latest version of the publication cited.

**Table 2** Contaminant concentrations for organic compounds in drinking water

	<i>Description and possible sources of contamination</i>	<i>Sam. Loc.</i>	<i>WHO drinking water guideline value</i>	<i>USEPA maximum contamination level (MCL)</i>	<i>USEPA recommended method</i>
Acrylamide	Minor impurity of polyacrylamide (flocculant aid)	TW	0.5 µg l <sup>-1</sup> <sup>p</sup>	Treatment chemical: <0.5 µg l <sup>-1</sup>	Polarography, GC-ECD, HPLC-UV
Benzene	Could occur in drinking water from atmospheric deposition and chemical plant effluent. Human carcinogen	RW	10 µg l <sup>-1</sup> <sup>p</sup>	5 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Carbon tetrachloride	Impurity of chlorine used for disinfection (it is not disinfection by-product) or discharge from chemical plants	TW	2 µg l <sup>-1</sup>	5 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS, Liq-Liq Ext GC-ECD
Chlorobenzene	From spills/discharges	RW	300 µg l <sup>-1</sup> , 10–120 µg l <sup>-1</sup> <sup>*</sup>	100 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Dichloroethanes (1,2-dichloroethane)	From industrial effluents, spills, discharges	RW	30 µg l <sup>-1</sup>	5 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Trichloroethane (1,1,1-trichloroethane)	Same as dichloroethanes	RW	2000 µg l <sup>-1</sup> <sup>p</sup>	200 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS, Liq-Liq Ext GC-ECD
Dichloromethane (methylene chloride)	Widely used solvent, commonly found in ground water	RW	20 µg l <sup>-1</sup>	5 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Epichlorohydrin	Used in manufacture of some resins used in water treatment	TW	0.4 µg l <sup>-1</sup> <sup>p</sup>	Treatment chemical: <2 µg l <sup>-1</sup>	GC-MS, GC-ECD, GC-FID
Ethylbenzene	Natural component of petrol and petroleum products	RW	300 µg l <sup>-1</sup> , 2–200 µg l <sup>-1</sup> <sup>*</sup>	700 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Haloacetic acids	By-product of chlorination	DS	NAD	0.06 mg l <sup>-1</sup>	Ion-Ex Liq-Solid Ext GC-ECD, Liq-Liq Ext GC-ECD
Di(2-ethylhexyl) adipate	Plasticizers used in all PVC products and may leach over a long time from linings in water storage tanks and distribution lines. Could also occur in drinking water as spills	SC	80 µg l <sup>-1</sup>	400 µg l <sup>-1</sup>	Liq-Liq Ext GC-PID, Liq-Solid Ext GC-PID, Liq-Solid Ext GC-MS
Di(2-ethylhexyl) phthalate	As above	SC	8 µg l <sup>-1</sup>	6 µg l <sup>-1</sup>	Liq-Liq Ext GC-PID, Liq-Solid Ext GC-PID, Liq-Solid Ext GC-MS
Benzo(a)-pyrene	One of a group of compounds. Polycyclic aromatic hydrocarbons (PAHs). Leaching from linings of water storage tanks	SC	0.7 µg l <sup>-1</sup>	0.2 µg l <sup>-1</sup>	Liq-Solid Ext GC/MS
Pesticides and related compounds	Pesticides should only be authorized for use in water or water catchment areas where necessary. Pesticides not authorized for uses should not be present in drinking water. Contamination by pesticides may occur as a result of accidental spills	RW	Low µg l <sup>-1</sup> range <sup>+</sup>	Low µg l <sup>-1</sup> range <sup>+</sup>	Requires sample preconcentration followed by one of the methods listed: GC-ECD, GC-NPD, GC-MS, LC-UV, LC-fluorescence

Styrene (vinylbenzene)	Industrial contaminant, discharge from rubber and plastic factories. Leaching from landfills	RW	20 µg l <sup>-1</sup> , 4–2600 µg l <sup>-1</sup> *	100 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Trihalomethanes (THMs) (total)	By-product of chlorination, chloramination	DS	No value set	100 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS, Liq-Liq Ext GC-ECD
Bromoform	By-product of chlorination, chloramination	DS	100 µg l <sup>-1</sup>	No value set	As above
Dibromochloromethane	By-product of chlorination, chloramination	DS	100 µg l <sup>-1</sup>	No value set	As above
Bromodichloromethane	By-product of chlorination, chloramination. Considered to be carcinogenic	DS	60 µg l <sup>-1</sup>	No value set	As above
Chloroform	By-product of chlorination, chloramination. Considered to be carcinogenic	DS	200 µg l <sup>-1</sup>	No value set	As above
Toluene	Occurs naturally in petrol and natural gas, forest fire emissions. Could occur in drinking water from atmospheric deposition, industrial contamination, leaching from protective coatings in storage tanks	DS	700 µg l <sup>-1</sup> , 24–170 µg l <sup>-1</sup> *	1000 µg l <sup>-1</sup>	GC-PID/ELCD, GC-MS
Vinyl chloride	From chemical spills. Used in making PVC pipes. Human carcinogen	RW	5 µg l <sup>-1</sup>	2 µg l <sup>-1</sup>	GC-PID/ELCD, CG-MS
Xylene	Pollutant from solvent used for bonding plastic fittings	DS	500 µg l <sup>-1</sup> , 20–1800 µg l <sup>-1</sup> *	10 mg l <sup>-1</sup> (total xylenes)	GC-PID/ELCD, GC-MS

Sam. Loc. (sample location): RW – raw water, TW – treated water, DS – distribution system, and SC – supply to consumer 'consumer taps'.

NAD: no adequate data to permit recommendation of a health guideline value.

\*Aesthetic guideline value.

p: provisional guideline value.

+: Due to the number of pesticides listed in the original references, a general item as pesticides and related compounds is listed in the table. For individual guideline or standard values refer to WHO – *Guidelines for Drinking-Water Quality* (1993), USEPA – *National Primary Drinking Water Standards* (1999), and NHMRC/ARMCANZ – *Australian Drinking Water Guidelines* (1996).

Generally, organic compounds present in drinking water are in low µg l<sup>-1</sup> concentration. Organic analysis often coupled with a sample pretreatment step as part of the analytical procedure, Liq-Liq Ext: liquid-liquid extraction, Liq-Solid Ext: liquid-solid extraction, Ion-Ex Liq-Solid Ext: ion-exchange liquid-solid extraction.

Analytical techniques: GC, gas chromatography coupled with various detectors; ECD, electron capture detector; ELCD, electrolytic conductivity detector; FID, flame ionization detector; MS, mass spectrometry; NPD, nitrogen phosphorus detector; and PID, photoionization detector; LC, liquid chromatography with UV detector or fluorescence detector.

Methods recommended by WHO – *Guidelines for Drinking-Water Quality*, 2nd edn (1993), vol. 2, Health Criteria and other Support Information (shaded portions).

The detailed information of this table is obtained from WHO – *Guidelines for Drinking-Water Quality*, 2nd edn (1993), USEPA – *National Primary Drinking Water Standards* (1995), NHMRC/ARMCANZ – *Australian Drinking Water Guidelines* (1996), USEPA – *Methods and Guidance for Analysis of Water*, Version 2 (1999), and APHA – *Standards Methods for the Examination of Water and Wastewater*, 20th edn (1988). This table is produced to illustrate the contaminant of concerns and their concentrations in drinking water in relation to the analytical techniques used for the determination. For detailed analytical procedure, derivation of guideline/standard values and health-related concern of contaminant level in drinking water consult the original publication cited and more preferable to obtain the latest version of the publication cited.

guidelines and take into account local conditions. All these authorities use slightly different approaches to establish their standards or acceptance levels. Differences in the values set by authorities are usually due to a local or national problem. A list of contaminants and the maximum contaminant levels (MCL) recommended by the WHO and USEPA is presented in Tables 1 and 2. In addition, to ensure the supply of good-quality drinking water, there are also aesthetic (nonhealth based) guideline values recommended by WHO.

## Water Management Framework

There has been a strong focus on numerical standard values and limits and monitoring of these constituents for compliance to guarantee the safety of water supplies. Monitoring also enables appropriate preventive measures to be taken before failure or contamination occurs. A more proactive approach by using a preventive management concept has been described in the *WHO Guidelines for Drinking-Water Quality* and this strategy was recently developed by NHMRC/ARMCANZ into a water management framework, protection of water from source (catchment) through to the consumer. This approach encourages water authorities to manage their water supply systems by putting in more effort on understanding their entire systems and the development of preventive strategies necessary for ensuring the control of hazards entering the system and, if necessary, the removal of hazards using various treatment options.

### Catchment and Source Water Protection

Water collected from the environment contains trace quantities of dissolved and suspended matter of mineral, plant, and even animal origin, which may create color, taste, and odor. It is also very likely to contain a diverse population of microorganisms and chemicals that may put human health at risk. The protection of water sources from human or animal pollutants should minimize contamination.

### Water Treatment

**Clarification of water** The treatment of drinking water provides multiple barriers to protect public health by removing microorganisms, and natural and man-made chemicals that may cause illness in consumers. Generally, a conventional treatment process employs coagulation/flocculation–sedimentation–filtration, and various modifications of the above configuration can be adopted based on specific needs. Aluminum- and iron-based chemicals, particularly alum ( $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ ) and iron(III) chloride,

are widely used coagulants for drinking water treatment. The use of synthetic organic polymers to destabilize particles has gained acceptance as an alternative coagulant. Positively charged (cationic) polymers, such as polydiallyldimethylammonium chloride, are the most common types used. Other types of polymers are used as coagulant aids to aid the growth of the floc and can be applied to assist the treatment process.

Membrane filtration for drinking water treatment is a relatively new technology. This chemical-free process can be considered as an alternative to the conventional treatment process.

**Disinfection** The biggest risk to public health when managing the supply of municipal potable water arises from inadequate treatment of microbiologically contaminated water. Water should be disinfected before entering the distribution system. Agents and processes that have been used for the disinfection of water include chlorine, chloramines, chlorine dioxide, ozone, bromine, iodine, silver, and ultraviolet radiation. Generally, an adequate concentration of disinfectant should be maintained throughout the distribution system to prevent bacterial recontamination and regrowth.

### Distribution System

Moving water to the customer requires a network of mains, pipes, and, in some cases, service reservoirs for short-term storage. The size and complexity of water distribution systems vary dramatically but it is an important requirement that the distribution system has to be closed to prevent possible recontamination. Maintenance of distribution systems to prevent water quality deterioration by regular cleaning is recommended.

### Monitoring

Drinking water quality monitoring involves a wide range of water quality assessments encompassing the entire water supply system. Careful consideration should be given to the water quality characteristics to be analyzed, including sampling location and frequency, analytical method, recording, evaluation, and reporting, with the emphasis on putting more effort into understanding the entire water supply system. Monitoring can be separated into two categories, operational monitoring and performance monitoring. Effective operational monitoring is critical for confirming that individual barriers for controlling hazards are functioning properly and effectively. Data from operational monitoring are used as triggers for immediate short-term preventive and corrective actions

to operational processes to maintain drinking water quality. Performance monitoring includes regular sampling and testing to demonstrate conformance with guideline values and other regulatory requirements.

## Water Analysis

The main objective of analysis is to ensure the water supplied to the public meets the relevant standards and does not exceed the recommended concentration of hazardous chemicals. The analyses performed by the water laboratory for compliance purposes should be performed in an accredited laboratory and comply with the recognized standard for technical competence of testing laboratories. A complete analytical procedure should include information on sample handling (collection, transport, and storage), sample preparation (concentrate and separate), analysis (methods to identify and quantify components), analytical quality control (criteria), and reporting of analytical results.

### Sampling Locations

Location and frequency of sampling depends on variability, and also the purpose, such as aesthetic or health significance. Locations can include the raw water supplied to the treatment plant, the process streams during water treatment processes, the product water leaving the plant, and the various sampling points in the distribution system. The sampling points in the distribution system should include consumer taps to ensure no deterioration in water quality during transportation in the pipelines. Sample frequency should be high enough to enable the monitoring to provide meaningful information. For characteristics where the concentration does not change greatly within the distribution system, sampling the water at the treatment plant may be sufficient. However, for characteristics that vary in concentration during distribution, sampling should be undertaken throughout the distribution system including the point of supply to the consumer. It should be noted that the behavior of some parameters (e.g., disinfection by-products, residual chlorine, microbial quality) during distribution may vary from one system to another and is likely to require system-specific investigation. A list of sampling locations of the concerning chemicals is presented in **Tables 1** and **2**.

### Types of Sample

Three types of sample, grab, composite, and integrated, are primarily used in drinking water analysis. Grab samples are a single sample collected at a specific location at a specific time. They are often

referred to as a 'snapshot' of a location and only represent the composition of its source at the time and place of collection.

Composite samples are obtained by combining portions of multiple grab samples or by using specially designed automatic sampling devices. This type of sample can reduce sample number and the samples are more representative of heterogeneous matrices. However, the composite samples may lose the analyte relationships in individual samples and increase the potential for analytical interferences.

Integrated samples can be viewed as a different form of composite sample. Instead of combining the grab samples at different sampling times, integrated samples combine grab samples collected at different locations at the same time. It is commonly used to evaluate average composition across the width or depth of a river or reservoir.

### Sample Collection Methods

Samples are generally collected by one of the three distinct sampling systems: a manual sampling system, a system involving sampling lines, or automatic sampling systems. In each it is important that the sample taken for analysis is representative of the whole body of water being sampled, and that the sample is not altered by the sampling system.

Manual sampling systems involve minimal equipment but they are costly and time consuming for routine monitoring. They may simply allow a large (bulk) sample to be obtained, which is then divided into one or more sample containers appropriate to the subsequent analyses. Sometimes samples are required from known depths, for example, in a raw water reservoir, when a depth sampler will be needed. These devices can be lowered to the known depth and then opened and closed before being recovered to the surface. This type of sampling is usually done by sample collecting personnel.

Systems using sampling lines are commonly used in water treatment plants. Often the flow of samples within the line occurs as a result of the pressure differential between the bulk matter and the line outlet. Where this is not possible the sample must be pumped, sucked, or pressurized to the outlet. Each situation must be considered on its merits, so that the system does not affect determinands of interest, e.g., dissolved gases and volatile organics can be lost when using suction pumps and vacuum lines, or, if the sample is to be examined to identify particulate material (such as algae), peristaltic pumps may be inappropriate. In certain critical situations duplicate pumps and sample lines may be necessary, together with sample line backwash facilities, e.g., to provide

sample to online-supply intake-protection water-quality monitors. In these situations, buildup of biological 'slimes' must be avoided as biological activity may alter the chemical composition of the sample before it reaches the analyzer.

Automatic sampling systems usually consist of a sampling device incorporating a sampling line and a unit that automatically controls the collection of a series of samples and stores them either as discrete subsamples or bulked composite samples for subsequent collection. These units can usually be programmed as to the time over which an individual sample is collected, the number of samples to be taken in the period of sample collection, and the overall time of sample collection. These systems can eliminate human errors in manual sampling and can reduce labor costs. Automatic samplers may thus be used to provide samples which will give information on water quality variation with time, to enable sampling at inaccessible and unmanned sites and to allow composite samples to be prepared. Some more sophisticated automatic samplers can accept feedback signals from flow-measuring equipment so the flow-related composite samples can be taken. In all the situations mentioned above it is most important that the automatic sampler does not contaminate the sample and all component parts of the sampling device that come into contact with the sample are inert or are known not to alter the concentration of the determinand(s) of interest. For example, plastic components may be incompatible with certain compounds that react with the plastic parts or that can be contaminated by contact with them.

In any situation involving sampling lines where suspended material may be present, the flow rate in the line should be sufficient to stop it settling out. It is also necessary to allow sample lines to run to waste for sufficient time to change the total volume contained within the line before collecting the sample for analysis.

### Sample Storage and Preservation

Ideally, the collected samples should be returned to a laboratory immediately (within a few hours) for analysis. However, this may not always be possible. The sample is a dynamic system whose composition may change with time and some determinations are more affected by sample storage than others. However, there is no single method of preservation that is entirely satisfactory. Selection of preservation method is based on the determination to be made.

The choice of sample container material may be an important factor for maintaining sample stability and

it is one of the most important components of the analysis. Contamination may be positive with analyte being added to the sample by the material from, or passing through, the container. Sample containers must be free of analytes of interest, especially for very low analyte levels. Glass (both soda and borosilicate), polyethylene (both high and low density), and polypropylene are commonly used materials for sampling containers. More recently, the use of polycarbonate, poly(vinyl chloride) (PVC), poly(ethylene terephthalate) (PET), and polytetrafluoroethylene (PTFE) sample containers have been reported. Only the correct type should be used, as one material may be preferred over the other, e.g., silica, sodium, and boron may be leached from soft glass but not plastic. Absorption is also possible, involving unexpected losses due to sorption onto or reaction with the container or by passage through the container, e.g., trace level of pesticides and metals may sorb onto the walls of glass containers. Thus, hard glass or plastic containers are preferred. The protocol of rinsing the bottle three times with the sample before sampling should be adopted.

Some metals are subject to loss by adsorption, or ion exchange with, the walls of glass containers. These determinands are best collected in separate clean bottles and acidified with nitric acid to a pH below 2. For most metal contaminants listed in **Table 1**, plastic or borosilicate glass sampling bottles can be used with the addition of  $\text{HNO}_3$  to pH <2 for sample preservation. Only refrigeration is recommended as sample preservation method for chromium and quartz or a PTFE sampling bottle for boron with addition of  $\text{HNO}_3$  to pH <2 for sample preservation.

Sample preservation for chloride and fluoride is not required. Fluoride should only be collected using plastic sampling bottles. Sample preservation of cyanide requires the addition of NaOH to pH >12 and refrigeration in the dark. Hydrogen sulfide requires the sampling bottle to be completely filled (no air gap) with minimum aeration. No sample preservation method is recommended for nitrate and nitrite, although it is generally required for the analysis to be carried out as soon as possible (within 1 day). Refrigeration for sulfate is essential.

For taste and odor analysis, only glass bottles can be used and analysis should occur as soon as possible. No sample preservation method is required for pH, although immediate analysis is recommended. Refrigeration is recommended as a sample preservation method for color measurement.

Disinfection agents, such as chlorine and chloramine, should be analyzed immediately. Addition of a quenching agent is required for disinfection by-products analysis. For inorganic disinfection

by-products, such as bromate and chlorite, the addition of 50 mg l<sup>-1</sup> ethylene diamine is recommended. For organic disinfection by-products, such as trihalomethane and haloacetic acid, the addition of sodium sulfite or ascorbic acid and ammonium chloride is recommended, respectively. It is more practical to predispense the quenching agent into the sampling bottle before sample collection to improve sample stability during transportation. In such instances, the sample should simply be filled to the appropriate level and a rinsing protocol should not be used.

Sampling for organic analysis is a rather complex issue as different analytes require different sampling protocols that are specific on sampling container type, sample preservation method, etc. Generally, the plastic sampling bottles are the preferred sampling containers and are required to be completely filled (no air gap), and refrigeration is highly recommended for sample preservation.

In general, when sampling for radioactive elements, concentrated hydrochloric or nitric acid is added at the time of collection to obtain a pH <2 and the sample held at this pH for at least 16 h before analysis. Microbiological samples should be collected using nonreactive borosilicate glass or plastic bottles that have been cleaned, rinsed, and sterilized. It is also very common for some analyses with the addition of a reducing agent, such as sodium thiosulfate, to dechlorinate the sample that prevents the continuation of bactericidal action during sample transit.

As a rule of thumb, during sample transportation, the preferred preservation procedure is to keep the sample cool at ~4°C. If analysis is to be delayed in the laboratory, sample refrigeration is required. The sample preservation methods described above are only a small number of examples to illustrate sample preservation methods with respect to the analyte of interest, for specific details of individual sampling methods consult APHA (1998).

### Sample Pretreatment

There is a common requirement in water analysis to separate the dissolved or suspended component in the sample before analysis. This is usually achieved by a physical separation step. Filtration is the most commonly used sample pretreatment method. Membrane and glass fiber filters are available in a variety of pore sizes and membranes are available in different materials. Water analysts normally use GF/C glass fiber filters for suspended solids determinations and 0.45 µm cellulose-based filters to define the soluble/insoluble fraction in samples. However, all filters and filtration apparatus must be checked to confirm

that they do not introduce contamination during the separation procedure. In trace metal analysis, it may be necessary to use PTFE-coated apparatus.

Four types of analyses can be performed in metal determinations, dissolved, suspended, total, and acid extractable metals, based on different sample pretreatment steps. The term 'total metals' includes all inorganically and organically bound metals and requires a vigorous digestion step of the unfiltered sample before analysis. 'Dissolved metals' determination requires filtration of unacidified sample that passes through a 0.45 µm membrane filter. 'Suspended metals' refer to the metals that are retained by a 0.45 µm filter. 'Acid-extractable metals' are determined after the unfiltered sample is treated with hot dilute mineral acid before analysis.

There are also sample concentration/separation techniques used as pretreatment methods for trace analysis. Commonly used methods include chelating ion-exchange and, for trace organic analysis, solvent extraction, carbon adsorption, and resin adsorption using nonionic macroreticular resins.

Minor variations in microbiological analyses can cause significant changes in results. Extra care is required for sample handling. General laboratory apparatus such as glassware, transfer pipettes, vials, and filtration equipment including disposable syringe filters are generally required to be sterilized before use.

### Analytical Techniques

Inorganic analysis, particularly metal analyses, generally falls into the category of spectrometry, which includes atomic absorption spectrometry (AAS) with flame or electrothermal atomization or the more advanced inductively coupled plasma with atomic emission spectrometry (ICP-AES) or mass spectrometry (ICP-MS). Other techniques such as colorimetry, ion-selective electrode (ISE), and ion chromatography (IC) can be used for anion analysis.

Analytical techniques such as gas chromatography (GC) and liquid chromatography (LC) are used for organic analysis. With the use of sample preconcentration steps such as liquid-solid, liquid-liquid extraction, solid-phase extraction (SPE), etc., or the powerful 'coupled techniques', such as GC-MS, a concentration range down to nanograms per liter can be determined.

A list of USEPA-recommended analytical methods corresponding to the contaminants stated in the WHO guidelines and USEPA standards is presented in **Tables 1 and 2**.

However, there are situations where the guideline value has been chosen for the purpose of determining

the presence of the chemical in the water. The guideline value for some chemicals, such as pesticides, has been set at the detection limit of determination, particularly pesticides that are not authorized to be used in certain areas. It is recognized that there are many experimental uncertainties in measuring extremely low concentrations. The limit of determination is often set as low as five times the detection limit, and is usually verified by interlaboratory tests.

By following good laboratory practice, such as including minimum required quality control for each analysis, the overall accuracy and precision of the test results can be assured. A good analytical quality control program should consist of at least some of the following elements: initial and ongoing demonstration of ability, method detection limit determination, reagent blank, blank spike, matrix spike, duplicate sample, internal standard, calibration, control charts, and quality control acceptance criteria.

## Introduction

Freshwater systems are highly dynamic and involve complex interactions between a variety of physical, chemical, and biological processes, e.g., water column–particle interactions, redox reactions, and bacterial activity. It is important to have an understanding of these processes for effective watershed management, which includes water quality issues. In this regard, high-quality analytical data, i.e., accurate and precise, are a prerequisite for predictive purposes, establishing water quality guidelines and monitoring compliance with legislation. Requirements vary from country to country but are primarily focused on three broad classes of indicators: physicochemical

(e.g., pH, temperature, turbidity, hardness), chemical (e.g., contaminants such as pesticides and heavy metals and nutrient species such as nitrate and phosphate), and biological (e.g., community structure, abundance, and biomass). Ideally, the chemical composition of the water being analyzed should be measured *in situ* on a frequent (or even continuous) basis. When this is not possible a comprehensive sampling/analysis program with rigorous quality assurance, as shown in **Figure 1**, should be adopted. Minimizing sample contamination and/or degradation during sampling and storage is a key aspect of the program.

The chemical quality of surface water in rivers and streams, lakes, ponds, and wetlands is determined by interactions of the water body with, for example, soil/sediment, suspended solids, rocks, groundwater, and the atmosphere and by in-water biological, chemical, and physical processes. It can also be significantly perturbed by agricultural and industrial inputs that are often classified in terms of point sources (e.g., discharge of effluent from a factory or sewage treatment plant outfall pipe) and diffuse sources (e.g., runoff from agricultural land). There

the presence of the chemical in the water. The guideline value for some chemicals, such as pesticides, has been set at the detection limit of determination, particularly pesticides that are not authorized to be used in certain areas. It is recognized that there are many experimental uncertainties in measuring extremely low concentrations. The limit of determination is often set as low as five times the detection limit, and is usually verified by interlaboratory tests.

By following good laboratory practice, such as including minimum required quality control for each analysis, the overall accuracy and precision of the test results can be assured. A good analytical quality control program should consist of at least some of the following elements: initial and ongoing demonstration of ability, method detection limit determination, reagent blank, blank spike, matrix spike, duplicate sample, internal standard, calibration, control charts, and quality control acceptance criteria.

## Introduction

Freshwater systems are highly dynamic and involve complex interactions between a variety of physical, chemical, and biological processes, e.g., water column–particle interactions, redox reactions, and bacterial activity. It is important to have an understanding of these processes for effective watershed management, which includes water quality issues. In this regard, high-quality analytical data, i.e., accurate and precise, are a prerequisite for predictive purposes, establishing water quality guidelines and monitoring compliance with legislation. Requirements vary from country to country but are primarily focused on three broad classes of indicators: physicochemical

(e.g., pH, temperature, turbidity, hardness), chemical (e.g., contaminants such as pesticides and heavy metals and nutrient species such as nitrate and phosphate), and biological (e.g., community structure, abundance, and biomass). Ideally, the chemical composition of the water being analyzed should be measured *in situ* on a frequent (or even continuous) basis. When this is not possible a comprehensive sampling/analysis program with rigorous quality assurance, as shown in **Figure 1**, should be adopted. Minimizing sample contamination and/or degradation during sampling and storage is a key aspect of the program.

The chemical quality of surface water in rivers and streams, lakes, ponds, and wetlands is determined by interactions of the water body with, for example, soil/sediment, suspended solids, rocks, groundwater, and the atmosphere and by in-water biological, chemical, and physical processes. It can also be significantly perturbed by agricultural and industrial inputs that are often classified in terms of point sources (e.g., discharge of effluent from a factory or sewage treatment plant outfall pipe) and diffuse sources (e.g., runoff from agricultural land). There

**Figure 1** Schematic of a well-organized sampling/analysis protocol for freshwaters.

can be a strong seasonal trend with some chemical parameters (e.g., nutrients) and major short-term fluctuations due to, for example, rainfall events and pollution incidents. Whilst legislation usually requires concentrations of chemical parameters to be monitored, management issues are often better addressed by determining seasonal or annual fluxes (or loadings), which is also a function of the flow regime for rivers. Determination of the chemical variables to be measured, sampling locations, and frequency of sampling depends on the objectives and economics of the monitoring program. The choice of analytical method will also be a function of detection limit, precision, accuracy, speed, and cost.

## Sampling Protocol

A fundamental requirement of any sampling protocol is that the sample is representative of the body of water from which it originates. Therefore, a well-organized protocol should retain, as closely as possible, the original composition of the freshwater body in the collected sample. Procedures should be kept as simple as possible while minimizing the possibility of contamination or interferences from foreign substances. It is important to collect samples from the water column at a series of depths and cross-sectional locations as manual grab samples or through the use of automatic samplers that can be

programmed to collect samples at specific time intervals or flow-dependent intervals. Commercially available sondes (*in situ* probes) can be deployed in parallel with samplers to log parameters such as pH, dissolved oxygen, temperature, and turbidity and can transmit these data from remote sites via telemetry systems mounted above the water level.

It is also essential to monitor flow rates in rivers so that concentration data can be converted to flux data. This is typically done automatically every 15 min at gauging stations and again these data can be transmitted back to a central laboratory by telemetry. In addition, it is important to avoid boundary areas, for example, confluence of streams or rivers and below sewage treatment works (STWs) unless their impact on the water body is being investigated. Point source contributions from STWs, for example, will affect the overall water quality of freshwater systems, particularly the input of nutrient elements in the form of, for example, phosphate, ammonia, and nitrate.

In lakes and reservoirs, representative sampling is often difficult due to environmental heterogeneity, both spatial and temporal, due to, for example, thermal stratification and ecosystem dynamics. For example, during summer, deep lakes can be subdivided into a relatively uniform, warm, circulating upper region (epilimnion), a deep, cold, relatively undisturbed region (hypolimnion), and a region of

rapid temperature change between the two (thermocline). In addition, localized physical conditions (e.g., isolated bays and inflowing rivers or streams) must be considered to ensure that sampling objectives are not compromised.

Sampling depth is a key parameter when analyzing groundwater and special borehole sampling devices are required, with modified samplers for unstable determinands. There are various pumping mechanisms in use such as suction lift, positive displacement, and those that use inert gas to drive the groundwater to the surface. When considering treated water sources, for example, household taps, care must be taken that the water has not been standing in the pipes for a long period of time. A good flush of the pipes should be given, unless the object of the program is to measure contamination from the pipes, for example, leaching of lead.

Sampling of interstitial waters is particularly challenging due to the potential for the sampling process to perturb the system by, for example, sorption and/or contamination from the sampler and changes in redox state and pH. Five commonly used methods are: centrifugation, centrifugal drainage, basal cup, vacuum filtration, and dialysis.

### Site Selection

The selection of the number and location of sampling sites is crucial in any sampling protocol and will ultimately depend on proper authoritative permission for access and the objectives of the sampling program. It is paramount that sites are safe and accessible for personnel and equipment. In addition, locations must be chosen so that the samples taken are representative of the body of water at the site.

### Safety

Safety is of vital importance as the possibility of bacteriological, virological, and zoological hazards exist in many freshwater locations. Weil's disease, caused by the *Leptospira bacterium*, is one example of an infectious disease that is transmitted by infected animals into freshwater bodies, especially downstream from sewage works or runoff from landfill sites. It is thus recommended that gloves and barrier creams be worn when sampling these locations. Sampling alone, regardless of site location, is not recommended. Details of the sampling site(s) and approximate times visited should be recorded prior to departure so personnel back at the laboratory are aware of your location. In addition, reliable communication should be established between the laboratory and field location in case any emergencies or technical issues arise. Extra care should be taken

in extreme weather conditions such as heavy rain, storms, snow, and ice.

### Frequency and Cost

The frequency of sampling (e.g., one-off, hourly, daily, monthly, or occasional) will ultimately depend on the overall cost-effectiveness of the sampling protocol. In many freshwater bodies, the majority of the annual flux of contaminants (e.g., phosphorus) is transported during intense, short-term events (e.g., storms) when discharge is high. For example, phosphorus loadings in rivers and streams are generally higher during autumn and winter months when flows are highest, and lower in summer months when the flow is low and biological activity is high. Important in-water processes that affect phosphorus concentrations include plant and algal uptake, anthropogenic inputs (e.g., sewage effluent), matrix considerations (e.g., hardness), and resuspension of bottom sediments from increasing discharge.

Diurnal changes must also be taken into consideration. For example, the dissolved oxygen concentration in freshwaters is dependent on temperature (as well as depth, altitude, saline intrusion) and competing autotrophic (photosynthesis) and heterotrophic (respiration) processes, which leads to significant day/night variations. Thus, sampling at frequent intervals over 24 h periods is recommended when investigating these processes.

### Sample Treatment and Storage

Table 1 lists sample storage and treatment criteria for the determination of a number of parameters in freshwater environments. It is important to state that no single method of storage and preservation exists for all parameters, but the effectiveness of such methods depends on factors such as sample matrix, filtration technique, storage container, chemical addition (e.g., acidification), and physical treatment (e.g., refrigeration). When determining nutrients, for example, protocols should take account of the following general guidelines:

1. a rigorous cleaning procedure is essential to avoid contamination;
2. all sample containers should be made of a strong, inert material;
3. filtration (typically 0.45 or 0.2  $\mu\text{m}$ ) should be carried out at time of sampling with a low-pressure gradient (less than 1 atm) to avoid cell lysis; and
4. filtered samples should be analyzed as quickly as possible, ideally within 8 h to minimize nutrient loss.

**Table 1** Sample storage and treatment criteria for various parameters in freshwater samples

<i>Parameter/analyte</i>	<i>Storage container</i>	<i>Preservation method</i>	<i>Storage time</i>
Acidity and alkalinity	Polyethylene or glass	4°C	24 h
Ammonia	Polyethylene or glass	Acidify, filter	1 month
Arsenic	Polyethylene or glass	Acidify	1 month
BOD	Glass	4°C	ASAP, dark
Carbon, organic	Glass	Acidify with H <sub>2</sub> SO <sub>4</sub> , 4°C	ASAP, dark
Chlorides	Polyethylene or glass	4°C	1 month
Chlorophyll	Polyethylene or glass	4°C	24 h
COD	Glass	Acidify with H <sub>2</sub> SO <sub>4</sub> , 4°C	24 h, dark
Conductivity (onsite preferred)	Polyethylene or glass	4°C	24 h
Fluorides	Polyethylene	4°C	1 month
Iodides	Polyethylene or glass	4°C	24 h
Iron	Polytetrafluoroethylene	Acidify, filter	1 month
Lead	Polyethylene or borosilicate	Acidify, filter (do not use H <sub>2</sub> SO <sub>4</sub> )	1 month
Manganese	Polyethylene or borosilicate	Acidify, filter	1 month
Mercury	Polytetrafluoroethylene	Acidify, HNO <sub>3</sub> and K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> addition	1 month
Nitrate (matrix dependent)	High-density polyethylene	Filter, 4°C	1–2 months
Phosphates, TP (matrix dependent)	High-density polyethylene	Filter (species dependent), 4°C	1–2 months
Pesticides	Glass (solvent washed)	4°C	24 h
Selenium	Glass or borosilicate	Acidify to pH 1	1 month
Silicates	Polyethylene	Acidify with H <sub>2</sub> SO <sub>4</sub> , filter, 4°C	24 h
Sulfates	Polyethylene or glass	4°C	1 week
Surfactants	Glass	Specific to type	–
Total residue	Polyethylene or glass	4°C	24 h

ASAP = as soon as possible.

Chemical addition (to prevent biological growth) and matrix considerations are also important and are discussed in greater detail below.

### Sample Containers

Sample containers should be made of high-quality materials such as quartz, borosilicate glass, polyethylene, polypropylene, high-density polyethylene (HDPE), or polytetrafluoroethylene (PTFE). Special care must be taken so that the container does not contaminate the sample or remove analytes by adsorption. Glass or borosilicate containers, for example, can increase the silica and sodium concentrations of samples and provide active sites for removal of some metal ions. Fluorides react with glass and pesticides and hydrocarbons adsorb onto polyethylene containers. As shown in **Table 1**, polyethylene and HDPE are recommended for nutrients and trace metals. Glass is recommended for generic parameters such as biological oxygen demand (BOD) and chemical oxygen demand (COD) and for organic compounds such as pesticides.

### Cleaning Protocols

The walls of sample containers are excellent substrates for bacteria, often enhancing bacterial growth, and therefore rigorous cleaning of all laboratory-ware is necessary. For nutrient (e.g., nitrate and phosphate) determinations, containers should be cleaned overnight with a nutrient-free detergent,

rinsed with ultrapure water, soaked in 10% HCl overnight, and then rinsed with ultrapure water. For trace metals, plastic containers should be acid washed with a 1 M solution of nitric acid overnight then rinsed with ultrapure water. For organic compounds, including pesticides and herbicides, chromic acid washing of glass bottles is recommended, followed by ultrapure water and final rinsing with an appropriate organic solvent (e.g., hexane). In all cases, containers should be rinsed at least twice with the water of interest prior to analysis with blank measurements taken to ensure that contamination of samples is not occurring.

### Filtration

The process of sample filtration is often necessary in freshwater analysis, especially when particulate and dissolved fractions are measured separately. Generally, filtration is done using a 0.45 or a 0.2 µm filter, with the fraction passing through it operationally defined as soluble (or dissolved) and matter (both biotic and abiotic) collected on the filter defined as suspended. Filtering removes suspended particulate matter that can cause measurement interferences, for example, scattering of light in spectrophotometry. Filtering through a 0.2 µm filter removes the majority of bacteria and plankton that could otherwise alter analyte concentrations (especially nutrients) during storage.

As with sample containers, the filtration apparatus (including individual filters) must be cleaned prior to

use using similar acid wash/ultrapure water rinse procedures. The filtration procedure can be carried out under positive pressure or vacuum. However, excess pressure gradients should be avoided as rupture of algal cells and the subsequent release of intracellular contents into the sample could occur. Filters vary according to category (depth or screen) structure, pore size, and composition with the correct filter of choice ultimately based on the parameter of interest. For depth filters, the effective pore size changes as the filter becomes more loaded with particles, whereas screen filters are not affected by particle loading. The most widely used filters for water analysis are cellulose-based, glass fiber, polycarbonate, poly(vinyl chloride), and PTFE.

### Storage and Preservation

If immediate analysis is not possible, freshwater samples must be preserved and stored to maintain the original concentration of the analyte within the level of accuracy required by the particular program. A considerable body of literature presents varied opinions on the effectiveness of different preservation methods. However, cooling the sample (i.e., refrigeration and freezing) and acidifying are the most widely used and accepted methods of sample preservation.

For trace metals, sample acidification to a pH of below 2 is the most widely used form of sample preservation. This procedure not only helps eliminate biological growth, but also limits adsorption onto the container walls. For nutrients, it is difficult to select one reliable treatment due to specific matrix characteristics (e.g., hardness, salinity, dissolved organic matter, and bacterial nutrient uptake) of the sampling location. In chalk catchments where calcium concentrations are high, freezing samples is not recommended due to the possibility of inorganic phosphate being co-precipitated with calcite when thawing the samples. Storage at 4°C is highly recommended, often with the addition of chemical additives such as chloroform to prevent biological growth. However, chloroform should not be used in samples with a high organic matter content, as the release of cellular enzymes into the samples is possible.

### Analytical Techniques

There are several alternative methods of analysis available for each parameter in freshwaters, with the method of choice ultimately depending on

1. the range of concentrations that need to be determined;
2. the accuracy and precision required;

3. selectivity required;
4. the maximum time between sampling and analysis; and
5. the cost relative to the analytical objectives.

In view of the above-mentioned challenges associated with sample collection and analysis, it is desirable to monitor each parameter *in situ*. The most important consideration is the accuracy and precision of the data obtained in the most cost-effective manner. Table 2 gives a general overview of common analytical techniques for important chemical parameters in freshwaters.

### Flow Injection Analysis

Flow injection (FI) analysis has become an established tool for sample presentation and online treatment (chemical and physical) in the laboratory environment. It is now being increasingly considered for deployment outside of the laboratory, in both process and environmental locations, for *in situ* analysis. The versatility and adaptability of FI allows it to be used in many different applications with a variety of detection modes.

FI systems have been successfully used with spectrophotometric detection, for example, for the determination of nitrogen and phosphorus species in rivers and streams. It has also been used to determine anionic surfactants (e.g., sodium lauryl sulfate, sodium dodecyl sulfonate), chloride, and organophosphoric insecticides in freshwater bodies. FI also can be coupled with other analytical techniques for sample introduction purposes. Such methods include FI coupled with atomic absorption spectrometry for online preconcentration and separation of chromium species and with mass spectrometry for the determination of polar organic pollutants.

### Atomic Spectrometry

Atomic absorption spectrometry is commonly used to measure a wide range of elements as shown in Table 2. Such techniques as flame, graphite furnace, hydride generation, and cold vapor are employed. Measurements are made separately for each element of interest in turn to achieve a complete analysis; these techniques are relatively slow to use. More sensitive, but also more expensive, multielement analytical techniques such as inductively coupled plasma-atomic emission spectrometry and inductively coupled plasma-mass spectrometry can be used if lower ( $\mu\text{g l}^{-1}$  and below) detection limits are required. These detectors can also be coupled with separation systems if speciation data, e.g., Cr(III) and Cr(VI), are needed.

**Table 2** Common techniques for the analysis of various freshwater determinands

<i>Parameter/analyte</i>	<i>Technique</i>
Alkalinity	Titrimetry
Antimony	Atomic spectrometry
Aluminum	Atomic spectrometry
Barium	Atomic spectrometry
BOD	Measurement of dissolved oxygen after incubation
Bromide	Capillary electrophoresis, flow injection, ion chromatography
Cadmium	Anodic stripping voltammetry, atomic spectrometry
Calcium	Atomic spectrometry
Carbon dioxide	Titrimetry, by calculation (from pH and alkalinity measurements)
Carbon, organic	High-temperature combustion with IR detection, wet digestion with spectrophotometric detection
Chloride	Flow injection, ion chromatography, titrimetry
Chlorinated phenoxyacid herbicides	Gas chromatography with, e.g., MS detection, liquid chromatography
Chlorine	Titrimetry
Chromium	Atomic spectrometry, ion chromatography
COD	Titrimetry
Copper	Atomic spectrometry
Cyanide	Flow injection, ion-selective electrode, titrimetry, ion chromatography
Fluoride	Flow injection, ion chromatography, ion-selective electrode
Hardness, total	Titrimetry
Iodide	Atomic spectrometry, voltammetry, ion chromatography
Iron	Atomic spectrometry, flow injection
Lead	Atomic spectrometry, anodic stripping voltammetry
Magnesium	Atomic spectrometry, ion chromatography
Manganese	Atomic spectrometry
Mercury	Atomic spectrometry
Nickel	Atomic spectrometry
Nitrogen (various forms)	Flow injection, ion chromatography, ion-selective electrode, titrimetry
Organochlorine insecticides	Gas chromatography with, e.g., MS detection
Organophosphorus pesticides	Gas chromatography with, e.g., MS detection
Polynuclear aromatic hydrocarbons	Gas chromatography, liquid chromatography
pH	Ion-selective electrode
Phosphorus (various forms)	Flow injection, ion chromatography
Potassium	Atomic spectrometry, ion chromatography
Selenium	Atomic spectrometry
Silicon	Flow injection analysis
Silver	Atomic spectrometry
Sodium	Atomic spectrometry, ion chromatography
Sulfate	Capillary electrophoresis, flow injection, ion chromatography
Turbidity	Nephelometry, potentiometry
Vanadium	Atomic spectrometry
Zinc	Atomic spectrometry

### Separation Techniques

Chromatography coupled with a suitable detector is the preferred approach for the determination of specific organic compounds in freshwaters. The most common techniques are liquid chromatography (LC) and gas chromatography–mass spectrometry, but LC coupled with mass spectrometry and multi-stage separations are becoming increasingly popular. Ion chromatography is extensively used for the determination of a wide range of cations and anions. Solid-phase techniques using chromatographic stationary phases, ion-exchange resins, and chelating ligands are also used for preconcentration of analytes from freshwaters prior to quantitative detection.

### Ion-Selective Electrodes

Ion-selective electrodes (ISEs) are potentiometric sensors that include a selective membrane to minimize matrix interferences. The most common ISE is the pH electrode, which contains a thin glass membrane that responds to the  $H^+$  concentration in a solution. Other parameters that can be measured include fluoride, bromide, nitrate, and cadmium, and gases in solution such as ammonia, carbon dioxide, nitrogen oxide, and oxygen. ISEs do have their limitations including lack of selectivity and sensitivity and problems connected with conditioning of electrodes. Detection limits for nitrate-N, for example, are typically  $\sim 0.098 \text{ mg l}^{-1}$  for commercial field devices and have chloride as a major interferent.

## Quality Assurance

A wide range of analytical techniques are used to determine freshwater parameters (see Table 2). It is therefore essential that quality assurance protocols are in place to ensure that consistently high-quality data (i.e., accurate and precise) are obtained. Specific techniques used to ensure the quality of measurements in terms of accuracy and precision are given below.

### Controls and Blanks

In-house quality control samples provide a day-to-day check of variability due to factors such as instrumental effects, different operators, blanks, and environmental effects. Laboratories often spike samples with a known amount of analyte, then estimate the recovery, and hence infer the accuracy of the method used. It is assumed that any interference will affect the spike in a similar manner as the unspiked sample.

Method and instrument blanks and, where possible, field blanks should be analyzed with each batch of samples. A method blank uses water, usually high-purity (double-distilled and deionized) water, which is processed through all laboratory steps in the same way as samples. An instrument blank uses the same water directly introduced into the detector. A field blank is high-purity water that has been bottled in the laboratory, shipped with sample bottles to the sampling site, processed, and preserved as a routine sample and returned with the routine samples to the laboratory for analysis. The analysis of a blank should not yield a value higher than that allowed by the acceptance criteria. Blanks are used to determine the limit of detection of a method and to monitor all aspects of the analytical process.

### Certified Reference Materials

Certified reference materials (CRMs) are materials of known analyte concentrations with a similar matrix to the sample being analyzed that are certified by technically valid procedures accompanied by or traceable to a certificate or other documentation issued by a certifying body. CRMs play important roles in helping produce reliable results including calibration and verification of measurement processes, quality control, verification of standardized methods, and the development and validation of new methods.

### Interlaboratory Comparisons

Individual laboratories can compare their results with consensus values generated by several laboratories after analyzing one or more homogeneous and stable materials under designated conditions. Interlaboratory comparisons between expert laboratories

play a major part in the production of CRMs. They can be used to compare the precision and accuracy of results between laboratories, provide impartial evaluation of in-house quality control procedures, identify best practice, and support training needs and provide valuable databases of analytical information.

## Data Management and Reporting

In view of the large amount of data that can be collected when analyzing freshwater samples, it is necessary to properly archive it in order to effectively interpret and report the results. With current computer technologies, databases, and online access, data management has become an easier and more reliable process.

All freshwater monitoring programs must clearly identify the end users' needs, with the reporting system efficiently and accurately transmitting the analyzed data. Time frames to submit the data should be established in advance and allow for any unforeseen complications. In addition, defining the type of transmission or presentation appropriate for each end user is paramount.

## Seawater – Organic Compounds

M R Preston, University of Liverpool, Liverpool, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The analysis of dissolved organic compounds in seawater is a complex task that poses a considerable number of challenges for the analyst. This article reviews the major problems and describes techniques for overcoming them or circumventing them using recent technological developments. Examples are given of the techniques that have been applied to a number of specific compounds or groups of compounds.

### Basic Considerations

The qualitative and quantitative analysis of organic compounds dissolved in seawater is difficult for at least four main reasons. First, the size and depth of the oceans makes the primary step of accessing the required sample dependent not only on the availability of suitable ships and ancillary equipment but also on such environmental conditions as wind speed and sea state. The quest for *in situ* samplers/sensors or analytical devices has been the focus of considerable efforts in recent years and some of these developments are discussed later. A second problem is that once the sample has been obtained, the high ionic strength of seawater presents other analytical challenges such that many methods applicable to freshwater systems cannot be applied to seawater. Third, the concentrations at which organic compounds normally occur in marine waters are extremely low and frequently fall within the nanomolar or sub-nanomolar range. Finally, the number of individual organic compounds present is effectively infinite because of the presence of the so-called marine uncharacterized material (UCM, also known as the uncharacterized fraction, geopolymer, or Gelbstoff), which is the highly complex persistent material formed by the degradation of plant- and animal-derived material.

The main problems confronting the marine analytical chemist are those of selectivity and sensitivity. In practice, there are comparatively few single techniques that can adequately address both of these requirements. In general, most instrumental methods are applied after some form of preconcentration step and commonly rely on gas (GC) or liquid (LC) chromatography to provide adequate separation of individual components and mass spectrometry (MS) for

detection. MS is not as sensitive a detection method as, for example, fluorescence but its great virtue is that of selectivity, particularly in ion-selective monitoring mode. Only recently have MS systems been made robust enough to take to sea and the very new development of submersible MS devices is opening up new possibilities in this area.

In the following sections aspects of organic component analysis in seawater are considered from sample collection through bulk or individual class analysis to individual component analysis. For interested readers the most useful general manual for seawater analysis is probably that by Grasshoff *et al.* A summary of some analytical strategies for analysis of organic compounds in seawater is given in Table 1.

### Sampling

The procedures used for the collection of samples at sea may be divided into the two categories of discrete and *in situ* procedures. Whilst the former approach is considerably more common, there are issues as to whether representative samples can be collected in this way. Large sample volumes and the greatest possible number of individual samples are the preferred options though both criteria are normally overridden by practicalities.

#### Discrete Sample Collection

Collection of samples for organic component analysis has a number of special difficulties. The sampling platform (i.e., the ship) is a considerable source of organic material, notably hydrocarbons from fuel and lubricating oil residues and CFCs/halons from refrigeration and fire-fighting equipment. Considerable attention must therefore be paid to sample design such that the sampler can be deployed, retrieved, and the sample processed without exposure to external contaminants.

The sampler itself should be constructed from non-contaminating and, equally important, nonadsorptive material. The sampler should also be capable of being lowered through the sea surface closed so as to avoid contamination from the organic-rich sea surface microlayer. Unfortunately, there is no ideal sampler. The modified General Oceanics 'Go-Flo' bottles widely used by workers in the field of oceanic trace inorganic analysis are often the most suitable systems that are commonly available. In some cases (e.g., for halocarbons), special devices have been constructed to allow uncontaminated withdrawal for the sample

**Table 1** Selected analytical strategies for the analysis of various dissolved organic compounds in seawater

Analyte	Examples of methods employed
Alcohols	SPE microextraction, GS-MS
Amides	(1) Amide herbicides – preconcentration using SPMDs then bioassay. (2) Diethanol amides by solid-phase extraction–liquid chromatography–atmospheric pressure chemical ionization/electrospray ionization mass spectrometry (SPE–LC–APCI/ESI-MS)
Amino acids	$\alpha$ -Phthalaldehyde derivatization then reversed-phase LC with fluorescence detection. Chiral derivatization permits separation of optical isomers on standard LC columns
Amino sugars	Anion exchange LC
Aromatic monosulfonic acids	Ion-pair liquid chromatography
Carbohydrates	High-performance anion-exchange chromatography and pulsed amperometric detection (HPIC–PAD)
Dimethyl sulfide	Purge and trap or headspace followed by GC–FPD
Dioxins/dibenzofurans	Solid-phase microextraction, thermal desorption followed by GC–tandem MS
Ethers	SPE microextraction, GS-MS
Halocarbons	Purge and trap GC–ECD or GC–MS
Hydrocarbons	Preconcentration by (1) purge and trap (volatiles) and (2) solvent extraction. Analysis by GC–FID or GC–MS
Neutral sugars	LC (anion) with PAD
Nitriles	SPE microextraction, GS-MS
Nitrophenols	Liquid–liquid extraction using a hollow fiber membrane followed by HPLC
Nucleic acids	Preconcentration on a hydroxyapatite column, derivatization with ethidium bromide dye fluorescence detection
Phthalate esters	Solvent extraction or SPE followed by GC–FID
Phenols	SPE followed by LC with electrochemical detection
Proteins	Preconcentration using cross-flow ultrafiltration. Analysis with $^{13}\text{C}$ NMR pyrolysis GC–MS, LC–MS
Pyridines	SPE microextraction, GS-MS
Uronic acids	Freeze drying, isolation by cation exchange, spectrophotometric determination

from the sampling bottle itself. However, no sampler that is constructed from plastic can be considered entirely suitable for trace organic work. Various other materials have been used for trace organic sample collection including glass though the fragility of this material at sea raises its own problems.

### ***In Situ* or Online Sample Collection and Processing**

To avoid the problems attendant upon the collection of discrete samples, and also to allow much larger volumes of water to be sampled, a number of *in situ* systems have been devised. These generally consist of metered submersible pumping systems capable of drawing water first through a filter and then an adsorption column. The units can be deployed from ships or attached to remote moorings and often programmed to sample at particular times of day or tidal state. Such units are battery powered and are capable of processing several hundred or even thousands of liters of water. The great advantage of these systems is that the influence of external contamination sources is relatively low and the amount of material adsorbed onto the column is sufficient to reduce the analytical detection problems that would otherwise be encountered in the laboratory. The main disadvantages are cost, the time necessary for deployment, and the fact that each system can only produce a single data point. They are therefore

considerably limited in their ability to produce oceanographically useful data such as depth profiles or time series with the appropriate spatial or temporal resolution.

Recent advances in sample collection have included semipermeable membrane devices (SPMDs). These are cheap, passive samplers that rely on diffusion of compounds of interest through a membrane and into an absorbent such as triolein. Whilst only semiquantitative in most applications, they do provide a simulation of biological uptake in that the absorbent mimics the properties of living tissue.

Online collection/concentration of samples through the use of cross (tangential) flow ultrafiltration has also found a number of applications.

***In situ* analysis** The ultimate ambition of marine analysts for *in situ* analysis has now been realized with the advent of underwater MS units. These small, submersible units are presently restricted to relatively shallow depths (<300 m) and low mass ranges (<200 amu) but represent a major step forward in marine chemistry. Such units are available as quadrupole (Figure 1) or ion trap (Figure 2) configurations and can be used in moored or towed systems. Examples of the output from such systems are given in Figure 3. Introduction of samples is through membrane diffusion and the units have a deployment time of around a week at present.

**Figure 1** Schematic of the three-pressure-vessel system for the underwater membrane-introduction quadrupole mass filter system. ## Storage

There are no universally satisfactory techniques for the storage of seawater samples prior to analysis for dissolved organic compounds. Acidification and/or refrigeration or freezing have all been used, as have various preservatives such as mercuric chloride. Because of the very low concentrations and (frequently) high biological availability of many dissolved organic compounds, there are considerable dangers of sample loss, degradation, or contamination. There is therefore no substitute for the rapid on-board or preferably *in situ* analysis of samples where possible.

## Filtration

The separation of the organic material in marine water samples into dissolved and particulate phases is not straightforward. The distinction is made on operational rather than theoretical grounds in that organic compounds occur in a wide range of ‘particle sizes’ ranging from truly dissolved through macromolecular species, colloids, bacteria, viruses, and planktonic species and upwards. The choice of filter medium can have a significant impact on the compounds falling into either the ‘particulate’ or

‘dissolved’ categories and the concept of a ‘third’ or ‘colloidal phase’ (i.e., a solid phase that has passed through a filter) has sometimes been invoked to explain the results of adsorption studies.

The problems arising from the filtration process are as follows:

1. It is not normally clear precisely what range of particles sizes are being retained on a particular filter medium and how these may change as the load on the filter increases within a single sample.
2. Some filters (notably membrane ones) may be supplied loaded with wetting/stabilizing agents that are organic in nature and must be removed before the filter is used if contamination of the filtrate is to be avoided. Glass fiber filters must be pre-ashed (normally by heating at ~400–450°C for several hours) to remove organic contaminants but it is probable that this process may lead to the formation/exposure of active sites within the filter capable of adsorbing sample components (see (iii) below). Other filter materials such as polytetrafluoroethylene (PTFE), aluminum, or silver membrane are sometimes used albeit at significant extra expense.
3. The filters used are not inert and may actually retain dissolved organic material on active sites on

**Figure 3** Laboratory data from ion trap MS analysis of water samples that were obtained during towed-deployment of the quadrupole MS system. The  $m/z$  78 ion is diagnostic of benzene and the  $m/z$  91 ion is diagnostic of toluene. Analyses of samples are compared with 1 ppb standards. (Reprinted with permission from Short RT, Fries DP, Kerr ML, Lembke CE, Toler SK, *et al.* (2001) Underwater mass spectrometers for *in situ* chemical analysis of the hydrosphere. *Journal of the American Society for Mass Spectrometry* 12: 676–682; © The American Society for Mass Spectrometry.)

the fiber surfaces. This is particularly true of glass fiber filters though it is a rarely considered issue.

4. The filtration process itself is a mechanically aggressive one for, in particular, delicate unicellular organisms such as the phytoplankton that are abundant in seawater. If performed without due regard for the problems such cells may rupture spilling their contents into the filtrate. In this regard vacuum filtration is probably only satisfactory if performed under weak ( $<0.25$  bar) vacuum and pressure filtration is generally more satisfactory.

5. The low concentrations of both dissolved and particulate species in seawater often requires that large volumes of sample be collected and processed. Special, large reservoir (e.g., 10–20 l) pressure filtration systems (commonly constructed of 316 grade stainless steel) are therefore needed and these are very expensive.

Recent innovations in filtration technology include tangential flow ultrafiltration methods that act as preconcentration methods for studies of marine biopolymers such as proteins (see also the section on Adsorption techniques below).

## Preconcentration

The low concentrations of dissolved organic species in seawater make a preconcentration step an almost mandatory component of the analytical process. Only

in rare cases (e.g., class analysis of primary amines) is such a step not incorporated. Two main approaches have been widely adopted for dissolved species namely solvent extraction and adsorption. Others such as co-precipitation or stripping of volatile species have been used in appropriate cases.

Many preconcentration steps require a subsequent cleanup stage and frequently a fractionation stage as well. Such steps greatly increase the times required for analysis and also considerably enhance the amount of sample handling required and hence the risks of contamination. A recent review of the subject of concentration techniques for isolating polar pesticides in environmental water samples has been produced (see Further Reading section). Many of these techniques have applications for other components of interest.

## Solvent (Liquid–Liquid) Extraction

A fairly limited range of solvents has been utilized for the extraction of trace organic species from seawater. Hexane is a common choice though many others have also been used. Recent trends have been to replace hexane with either pentane or heptane because of the lower toxicity of these alternatives. Strict regulations now apply to safety aspects of the use of solvents at sea and these must not be neglected by the marine analyst when devising new methodologies.

There are considerable practical problems in manipulating the large volumes of water (and solvent) required for seawater analysis. Sample volumes of up to, or exceeding 2–3 l, are required and the difficulties in manipulating such volumes, especially at sea, are considerable. Some large-volume continuous liquid–liquid extractors have been devised which are capable of use at sea though the practical difficulties associated with the operation of any fragile systems on ships should not be minimized. Such units may be capable of handling 10–20 l extractions.

## Adsorption

Preconcentration procedures using adsorption are now generally the preferred options. Adsorption techniques have considerable practical advantages over those utilizing solvent extraction, particularly when working at sea, because they offer the possibility of treating relatively large volumes of water, they are physically robust, and the extracted material can be returned to the laboratory in solid form. Selective adsorption methods have not been widely used in seawater analysis though ion-exchange methods have been used for amino acids in the past and for amino sugars and organic ligands more recently. Most techniques in common use today use nonspecific

adsorption onto materials such as Amberlite XAD-2 resin, Tenax resin, activated charcoal, polyurethane foam, zeolite, or variations on LC packing material such as octa or octadecyl silanized silica.

Traditional adsorption preconcentration techniques are based around the passage of filtered (and sometimes acidified or otherwise pretreated) water through a column of adsorbent. After passage of the sample the compounds of interest are eluted with an appropriate solvent or solvent mixture. Such techniques can be laboratory based, *in situ* (pumped systems or, more rarely, in passive towed units), or, in more recent systems, can be used in online applications.

*In situ* samplers capable of deployment to considerable (although not full oceanic) depths are now available. However, as mentioned above, these are of limited oceanographic usefulness in applications other than those requiring time-averaged concentration data at a very limited number of sites.

One of the main problems with solid adsorbents is that of obtaining satisfactorily low and reproducible blanks. Even if adsorbents can be adequately cleaned in the laboratory, very elaborate precautions must be adopted to prevent recontamination (and in the case of some synthetic resins, degradation) before deployment. Further problems may be encountered with *in situ* systems where the extended deployment times leave the sample (and adsorbent) vulnerable to bacterial attack.

An additional complication with solid adsorbents arises from the considerable variability of breakthrough volumes between different dissolved components. The high 'background' level of marine UCM tends to saturate the adsorption sites on some types of column before adequate amounts of the desired compounds have been extracted. Even within the UCM fraction there is some evidence to show that the adsorbed material changes in character with increasing sample volumes as compounds in the initial part of the sample volume that are only weakly adsorbed onto the column are displaced by more strongly adsorbed compounds arriving later in the process. The tendency in this case is often to displace low relative molecular mass and polar compounds with higher relative molecular mass and more hydrophobic materials.

The development of extraction disks (e.g., Empore<sup>TM</sup>) cartridges and syringe barrels has proved to be a convenient and attractive tool for the enrichment of trace organic materials from natural waters. Such units may consist of membranes of PTFE fibrils in between which are incorporated particles of adsorbent materials such as C<sub>8</sub>, C<sub>18</sub>, ion exchange resins, or polymer-based materials. These disks are in some ways more convenient than columns and may be

used in online or offline modes. Online is best suited to LC-based separation and detection systems whereas offline is generally more convenient with GC-based systems. One major advantage of the disks is that a number of them may be used in series. This feature allows the relatively efficient retention of sufficient quantities of compounds with relatively low breakthrough volumes. Column-based systems are less readily arranged in series and suffer from high back-pressure and/or low flows together with high dead volume which tend to enhance sample mixing during elution. Applications using hollow fiber membrane microextraction have recently been reported and have been reported to compare favorably with US EPA Method 508.

## Extraction of Volatiles

In recent years, there has been a marked increase in interest in the determination of volatile species in seawater. This interest derives from a number of areas such as the use of tracers in ocean water mixing studies, the quantitation of air-sea gas exchange processes, and oil exploration or pollution work.

A variety of techniques have been utilized, nearly all of which are relatively standard. Such methods include stripping techniques with solid phase and/or cryogenic trapping and followed by thermal desorption onto GC systems or passive 'equilibrium' headspace methods also followed by GC or GC-MS analysis. The development of underwater MS devices with membrane introduction of samples and a mass range (so far) up to 200 amu offers great future potential for volatiles work.

Well over 100 compounds have been determined in seawater (and sediments) using a considerable variety of techniques (Table 2). Methods include n- and branched alkanes (up to about C<sub>20</sub>, pristane/phytane), alkenes and aromatic compounds (up to the disubstituted naphthalenes), halocarbons and chlorinated aromatic species, low relative molecular mass alcohols, organic sulfur compounds (notably dimethyl sulfide, a major product of some phytoplankton species, but ranging up to dimethyl trisulfide), and freons (11, 12, and 113 used in studies of oceanic mixing).

## Direct Methods

As indicated above there are considerable problems involved in devising methods suitable for the direct determination of organic species in seawater but a number of techniques have been developed and these are described below.

**Table 2** Concentration ranges for a variety of volatile compounds extracted from estuarine waters<sup>a</sup>

Compound	Concentration range (ng l <sup>-1</sup> )
Methanethiol	10–73
n-Butane	28–60 199
2-Methylpropane	50–60 100
2-Methyl-1,3-butadiene	5–1233
n-Pentane	25–327
Isopentane	25–250
2-Methylbutene-1	50–700
Propanone	< 10–300
Dichloromethane	15–1004
Dimethylsulfide	10–814
Carbon disulfide	10–100
Propanal	30–300
Propanol-1	60–430
Propanol-2	70–300
Freon-113	25–70
Propanethiol	< 10–70
2,2-Diethylbutane	33–94
2,3-Dimethylbutane	38–109
Methyl <i>tert.</i> -butyl ether	15–81
Butanone-2	25–240
Butanone-1	25–200
n-Hexane	47–496
Pentanone-2	35–230
2-Methylpentene-1	130–700
Trichloromethane	10–7502
2-Methylfuran	10–17
1,2-Dichloroethane	15–955
1,1,1-Trichloroethane	< 5–2788
Benzene	100–55 380
2,2,3-Trimethylbutane	85–290
Carbon tetrachloride	< 10–311
n-Butanol	< 10–440
Thiophene	< 10–190
4-Methyl-2,3,-dihydrofuran	< 10–200
3-Methyl-2-butenal	< 10–180
1,2-Dibromoethane	< 10–176
Cyclohexane	30–801
Trichloroethylene	< 10–603
Pentenal	< 10–170
2,2,4-Trimethylpentane	< 10–400
2,4,4-Trimethylpentene-2	< 10–490
2,5-Dimethylfuran	< 10–50
n-Heptane	50–260
Methyl isobutylketone	< 10–347
Dimethyl disulfide	< 10–5250
Methylcyclohexane	< 10–100
1,1,2,2-Tetrachloroethylene	< 10–343
Methylbenzene	10–48 850
3-Ethylhexane	50–110
Chlorodibromomethane	10–2200
3-Methylthiophene	< 10–50
Hexanal	< 10–100
n-Octane	90–290
Octene-1	25–75
1,3-Dimethylbenzene	10–402 070
1,2-Dimethylbenzene	10–400 020
Chlorobenzene	< 10–120
Ethyl benzene	10–312 008
Tribromomethane	10–2597
Styrene	30–296
Dimethyl trisulfide	25–411

**Table 2** Continued

Compound	Concentration range (ng l <sup>-1</sup> )
n-Nonane	95–357
Nonene-1	90–300
Isopropylbenzene	10–47 307
1,5-Cyclooctadiene	< 10–400
Cyclooctene	< 10–380
$\alpha$ -Pinene	25–412
Camphene	25–99
2,4-Dimethyl-4-vinylcyclohexane	31–45
n-Propylbenzene	15–2391
Benzaldehyde	15–569
p-Cymene	35–45
1,3,5-Trimethylbenzene	20–1500
1,2,4-Trimethylbenzene	100–1570
1,2,3-Trimethylbenzene	50–6200
2,3-Dihydroindene	30–400
Limonene	25–633
Indene	55–277
1,2-Dichlorobenzene	35–107
n-Undecane	87–619
1-Methyl-3-propylbenzene	25–550
1-Methyl-2-propylbenzene	25–590
1,4-Dimethyl-3-ethylbenzene	25–200
1,3-Dimethyl-3-ethylbenzene	25–210
2,3-Dimethyl-4-ethylbenzene	30–100
1,3-Dimethyl-4-ethylbenzene	35–120
1,2,3,5-Tetramethylbenzene	25–1430
1,2,3,4-Tetramethylbenzene	150–8767
Naphthalene	45–894

### Analysis for Total Dissolved Carbon

The dissolved organic carbon (DOC) reservoir in sea water represents a very significant component of the oceanic carbon cycle but reliable quantitative determination of this parameter has proved to be difficult. For over a decade since the publication of Sugimura and Suzuki's Marine Chemistry paper there has been considerable debate about the most appropriate technique(s) for the determination of DOC in seawater. Techniques can be effectively divided into three categories:

1. (a) Removal of inorganic carbon and organic volatiles before analysis by acidification followed

- by gas stripping. (b) Continuous flow or flow injection methods utilizing UV or UV + chemical wet oxidation of the dissolved organic carbon to CO<sub>2</sub> followed by quantitative measurement using (generally) nondispersive infrared gas analyzers or by chemiluminescence.
2. (a) Removal of inorganic carbon and organic volatiles before analysis by acidification followed by gas stripping. (b) High-temperature catalytic oxidation followed by detection of evolved CO<sub>2</sub> using (mostly) infrared absorption.
  3. One recent study has employed inductively coupled plasma-atomic emission spectrometry methods for nonvolatile dissolved carbon analysis with detection limits of 0.07 and 0.0007 mg l<sup>-1</sup> C in terms of total organic carbon (TOC) and inorganic carbon (IC), respectively. However, this method is not widely used.

The debate over techniques (1) and (2) initially centered on the main component of the analytical technique (i.e., ‘wet-UV’ or ‘dry-high temperature’) but it has become apparent that the most significant difficulties with this measurement are more to do with analytical quality control issues such as the use of appropriate blanks, strict control of day-to-day operating conditions, and great care in calibration procedures. A very recent report by Sharp and co-workers on an extensive intercalibration exercise states that ‘Experienced oceanic analysts, with internal or shared reference materials, can now show reproducibility and comparability at a level closer to 2%’. The development of DOC reference materials is in its early stages and once such materials are reliably available then the DOC issue should settle down as a difficult but essentially routine measurement.

### Dissolved Organic Nitrogen and Phosphorus

Dissolved organic nitrogen (DON) and dissolved organic phosphorus (DOP) are receiving an increasing amount of attention from marine chemists because of the recognition that they represent more active components of their respective nutrient cycles than had previously been thought. Problems relating to the determination of total DON and DOP are very similar to those for DOC outlined above. Destruction of the organic matter by intense UV light to transform organic to inorganic species has been widely used. The nitrate + nitrite or orthophosphate formed may then be determined by classic colorimetric methods such as that involving the formation of either an azo dye by reactions with naphthylethylenediamine and sulfanilamide (for nitrogen) or a molybdenum blue complex (for phosphorus). These systems can be automated.

In the case of DON a high-temperature catalytic oxidation method has also been used for the initial step and whilst some of the same issues arise as for DOC determinations these are generally manageable.

### Analysis of Marine Uncharacterized Material

The importance of the marine uncharacterized material (UCM) fraction is that it represents a large proportion (~90%) of the total marine dissolved organic matter. It is very clear that the material is not a single substance but a highly complex mixture of polymeric (largely polyphenolic) degradation products that may range in relative molecular mass from a few hundreds to many (tens of) thousands with only a few group properties. These include the yellow/orange color from which the original German name (Gelbstoff) derived, a fluorescence emission maximum of ~430 nm and a monotonic absorption spectrum that increases into the UV. Whilst many attempts have been made to utilize the optical characteristics of UCM to assess its composition these have been largely unsuccessful although when used in combination with other methods (e.g., 3D spectrofluorometry, LC, and capillary electrophoresis (CE)) it has been possible, for example, to differentiate between marine and fresh water samples. Stable isotope analysis, <sup>13</sup>C nuclear magnetic resonance (NMR), CE, pyrolysis GC, and GC-MS techniques have also been utilized with some success.

Some recent progress has been made. For example, a recent study employing both proton NMR and monosaccharide analysis has suggested that there are at least two major classes of UCM. The major component is acyl polysaccharide, a biopolymer rich in carbohydrates, acetate, and lipid and that this can account for between 50% and 80% of the total high molecular weight dissolved organic carbon in surface samples.

### Specific Compounds or Classes

Procedures for the determination of biologically active compounds have to be capable of operation at sea. This considerably reduces the number of suitable methods so it is not surprising that such analyses are comparatively rare and restricted to a limited suite of compounds. Some of the available techniques are described below.

#### Amines

Amines form a major fraction of the characterizable marine DON fraction and most attention has been focused on primary amines (notably amino acids) in marine systems. Primary amines may be reacted with *o*-phthaldialdehyde in the presence of mercaptoethanol and at a pH of ~11.5 to yield highly fluorescent

isoindole derivatives. This reaction has been exploited in two different ways to assess either the total primary amine or the individual primary amines in seawater. A real-time, *in situ* total primary amine analyzer based on flow injection techniques has been developed for natural waters though the application has not yet been widely adopted for seawaters. The same reaction has been used as either a postcolumn or, more usually, a precolumn derivatizing agent in liquid chromatography. The precolumn derivatization is followed by separation by gradient elution on a C<sub>18</sub>, reversed-phase column with fluorescence detection and is capable of use at sea. The method is extremely sensitive and detection limits in the low femtomolar range for individual amino acids have been quoted when using large sample volumes. For routine applications detection limits in the picomolar range are probably more realistic. However, the method is quite difficult to perform reproducibly and, with such high sensitivity, contamination is a problem. Additionally, the acetonitrile required to give optimum resolution may not be acceptable aboard research ships. Nevertheless, the method has been successfully employed to determine over 20 amino acids in seawater. Recent developments in chiral chromatography are also beginning to find marine applications.

### Carbohydrates

Carbohydrates represent an important and biologically active fraction of the DOC components within seawater. The classical method in which carbohydrates have been reacted with hot concentrated sulfuric acid (to form furfural derivatives that are determined colorimetrically) has been applied to the analysis of total carbohydrates in seawater. This method is not very specific and has now been largely replaced by better (and safer) procedures. Examples of such methods for dissolved monosaccharides include: (1) Reducing them to the respective sugar alcohols, periodate oxidation to formaldehyde, and detection of this compound with 3-methyl-2-benzothiazoline hydrazone as a colored complex at 635 nm. This method is still relatively indiscriminate and will detect all glycol-containing compounds such as alditols, uronic acids, and amino sugars as well as the monosaccharides. (2) A more specific method involving the reaction of carbohydrates with L-tryptophan/sulfuric acid in the presence of boric acid to form a violet color. Monosaccharides and polysaccharides (hydrolyzed to monosaccharides by the sulfuric acid) may be determined with excellent precision at the mg l<sup>-1</sup> level. (3) Spectrophotometric analysis of a colored product of a reaction with the reagent 2,4,6-tripyridyl-s-triazine.

Individual dissolved monosaccharides have been determined after desalting of the sample by ion-exchange membrane electrodialysis followed by evaporative concentration and ion-exchange LC using colorimetric detection with Cu<sup>2+</sup>-aspartic acid-disodium-2,2' bichinchoninate. More recently a number of papers have described the use of anion-based LC with pulsed amperometric detection for individual monosaccharide analysis though it has been noted that temperature control of the system is particularly important.

### Urea

Recent studies have shown that urea is an important natural constituent of seawater but also derives from human uses of urea as fertilizer and is transported to the oceans primarily through the atmosphere as an anthropogenic source of DON. The most widely used reaction for urea determination is with diacetyl monoxime, semicarbazide, and manganous ions to produce a magenta-colored complex. Chloride and phosphate ions are also included in the reaction to improve sensitivity and reproducibility, respectively. The method has a detection limit of ~100 pmol l<sup>-1</sup>. The method is capable of being automated in a continuous flow system.

### Oil

Oil, and particularly crude oil, is the marine pollutant with the highest public profile and in most cases the most significant coastline contaminant. The need to determine dissolved oil concentrations in water is therefore a common requirement of pollution monitoring schemes. The chemical complexity of oil means that no single analytical method is ideal and the actual technique employed will normally be determined by the need of the analyst for more (or less) detailed information about the oil. In all cases the method selected is a trade-off between required details, time taken to complete an analysis, and the availability of equipment. For routine work, the commonest method is solvent extraction and quantitation by fluorescence measured at 360 nm. This procedure measures not only dissolved oil but also finely dispersed oil such as that commonly found after a spillage has occurred in rough weather. Problems of calibrating the method are addressed by using the source oil (if known and available) and/or chrysene solutions. Chrysene is accepted internationally as a standard for this purpose and oil concentrations are often reported as chrysene equivalents. Multidimensional contour plots of fluorescence excitation/emission spectra are sometimes used as an additional tool to 'fingerprint' dissolved oil samples as an aid to the identification of their sources.

For more detailed study of dissolved oil components GC and/or GC–MS techniques are generally used. The oil is solvent extracted from the sample and after a cleanup procedure may be directly injected into the GC. Interpretation of such data is generally difficult because of the degraded nature of the oil, the compound-selective nature of the dissolution process, and its mixture with other dissolved components. In practice, it is more common to analyze bulk oil samples from a slick rather than to examine the dissolved fraction. Only if there were a need to assess the extent to which the more toxic, water-soluble components were spreading within the water would such a detailed analysis be contemplated.

### Organic Contaminants Other than Oil

It can be assumed that virtually all reasonably persistent organic compounds used in human society will eventually find their way into the oceans through a combination of atmospheric transport and terrestrial runoff. The variety of compounds involved presents significant challenges to the analyst. The techniques for the determination of dissolved organic contaminants in seawater are generally very similar to those utilized for natural compounds. Adsorption onto Amberlite XAD-2 or polyurethane foam or, alternatively, solvent extraction into for example hexane, are common procedures. Cleanup using column chromatography, concentrated H<sub>2</sub>SO<sub>4</sub> (for chlorinated pesticides), or occasionally thin-layer chromatography are then followed by GC using flame ionization detection (FID), electron capture detection (ECD), or mass spectrometric detection. Less commonly LC is used with either UV absorption (including diode array systems) or fluorescence detection. LC–MS is also now finding applications in marine systems though largely in sedimentary biogeochemistry.

## Emerging Techniques

The primary ideal of the marine chemical analyst is to have access to equipment capable of providing real-time, *in situ* data for every chemical of interest, thus permitting the chemical data produced to provide the best possible insight into the myriad processes going on within the oceans. Needless to say this ambition is a very long way from being realized. However, there are one or two analytical areas where there are signs that progress could be made in this direction. The development of small, relatively rugged GC–MS systems for ship or *in situ* use represents the way in which many analyses of dissolved organic compounds in seawater will be performed in the future.

## Introduction

The anthropogenically induced increase of greenhouse gases (e.g., CO<sub>2</sub>) in the atmosphere has

triggered what is now widely recognized as the ‘global warming’ effect. Due to the potential adverse climatic conditions associated with global warming, interdisciplinary, international scientific environmental research programs (e.g., International Geosphere Biosphere Programme) in the past decade have increasingly focused on the global carbon cycle and the quantification of fluxes of atmospheric CO<sub>2</sub> at marine and terrestrial system interfaces. In part, these studies are aimed at resolving the discrepancies in the

estimates of carbon reservoirs and fluxes between reservoirs. Of particular importance is the dissolved organic carbon (DOC) pool in the oceans, being equivalent to that of atmospheric CO<sub>2</sub> (700 pg C). DOC is an important source of carbon for community respiration. Indeed, a net oxidation of only 1% of seawater DOC within a year would be sufficient to generate a CO<sub>2</sub> flux larger than that produced by fossil fuel burning. Hence, its accurate quantification in ocean systems, with both spatial and temporal variability, is one essential requirement in establishing a reliable global C budget. Furthermore, DOC is an essential chemical driver of aquatic biogeochemical cycles. It influences the distribution and transport of key chemical constituents such as inorganic nutrients and trace metals, and can facilitate the vertical export of aquatic colloids and associated material via aggregation processes. The reliable detection of DOC is thus crucial in our understanding of aquatic biogeochemical cycles.

## Historical Overview of Applied Analytical Techniques

Analytical techniques, which have been employed for the measurement of DOC in seawater, are (1) wet chemical oxidation (WCO), (2) ultraviolet (UV) oxidation, (3) dry combustion, and (4) high-temperature catalytic oxidation (HTCO).

Prior to the 1980s, WCO was the most adopted method; its application to DOC seawater analysis was first reported in the 1930s. Oxidants used have included peroxydisulfate, dichromate in sulfuric acid, and potassium peroxide. Prior to oxidation of the sample DOC, inorganic carbon was removed by purging of the acidified sample (pH < 2). The CO<sub>2</sub> produced from the oxidation process is measured by one of the number methods from nondispersive infrared gas analysis (IRGA), colorimetrically, and conductometrically by conversion to CH<sub>4</sub>. However, the limitation of WCO was the progressive weakening of the oxidant (particularly in the presence of Cl<sup>-</sup>), during sample treatment, which may have led to incomplete oxidation. Furthermore, different reagents would have had different oxidation strengths, potentially leading to different oxidation efficiencies.

UV oxidation methods were proposed during the same period as WCO, although they were not adopted until the 1970s. As with WCO, inorganic carbon is removed from the seawater prior to oxidation. Typically, water samples were exposed to a UV radiation source light via a quartz capillary coiled around the light source. Some UV radiation procedures included the addition of a chemical oxidant.

The advantage of the UV oxidation approach compared to that of WCO was that oxidants were generated continuously. However, the main disadvantage with UV oxidation was the deterioration of the UV light source with age. This lowered the efficiency of the oxidation process and potentially led to non-comparability of different research group datasets.

Dry oxidation methods (applied in the 1960s and 1970s) involved initial acidification and dehydration of the sample, followed by high-temperature combustion of the resultant 'sea salt'. Sample dehydration was achieved by heating to dryness at 60°C or by freeze-drying. The main disadvantage of these methods was the high degree of sample manipulation required during the dehydration step, enhancing the risk of sample contamination. The method is also labor intensive and cannot be automated preventing real-time analysis.

Since the late 1980s, HTCO methods, which typically incorporate an Al/Pt catalysis combustion column, have been adopted. The popularity of this technique was, in part, due to the advances in the sensitivity and stability of the IRGA and its real-time direct injection capabilities, requiring lower sample volumes (50–200 µl) compared to those for WCO (5–100 ml). HTCO is rapid and precise ( $\pm 1$ –2% RSD) and can yield equivalent or greater amounts of DOC than WCO methods. In addition, it is effectively adopted for routine analyses and is stable for ship-board determinations. This was first proposed in a paper by Sugimura and Suzuki, whose HTCO method detected 1.5–5 times higher concentrations of DOC (180–280 µmol l<sup>-1</sup> C) in surface oceanic waters than had been previously reported by WCO methods. Underestimation of the DOC concentrations in seawater measured by WCO would have clearly meant an underestimation of the DOC pool in the oceans. The findings of Sugimura and Suzuki, however, were not always reproduced by other researchers, and were subsequently retracted as a result of inaccuracies due to insufficient consideration of the influence of gases other than CO<sub>2</sub> and water/system blanks not subtracted from the initial data. Nevertheless, this work mobilized the scientific community into re-evaluating the accuracy of conventional WCO analytical techniques, and paved the way to the subsequent adoption of HTCO as the preferred analytical method for the determination of seawater DOC. Subsequent to Sugimura and Suzuki, research findings, both supportive and critical of the HTCO method, appeared but there were inconsistencies with the published data. This led to a US National Science Foundation/National Oceanic and Atmospheric Administration/Department of Energy sponsored workshop on the 'Measurement of Dissolved

Organic Carbon and Nitrogen in Natural Waters' (Seattle 1991) in order to critically evaluate the methodological procedures that essentially bear upon generating consistent results. In this workshop, natural seawater samples were distributed to 34 participants prior to the workshop for analysis to allow an intercalibration exercise to be performed. Poor comparability between laboratory analyses was apparent and values were within the mean values  $\pm 40\%$  RSD, although HTCO was confirmed as a more effective method than WCO. The inconsistencies were largely attributed to difficulties in the system blank correction.

In the last decade, HTCO has become the preferred analytical technique for the determination of DOC in natural water samples. With close attention to blank correction and sample treatment, HTCO measurements performed between analytical laboratories are now comparable and environmentally consistent.

This article focuses specifically on the HTCO technique currently in use for DOC analysis in seawater. The technique's hardware, principles, and typical analytical performance are critically presented, along with sample treatment and preservation methodologies.

## Current Procedure for the Measurement of DOC in Seawater

### Sample Collection

Changes in sample DOC composition may result from contamination, sorption onto container walls, and biological and flocculation processes. Due to the low background concentrations of DOC (typically  $40\text{--}50\ \mu\text{mol l}^{-1}\text{C}$ ) in marine waters, seawater samples are easily contaminated via: (1) the atmosphere (e.g., ship's engine exhaust fumes), (2) sampling bottles, and (3) careless handling (i.e., not wearing gloves, dirty laboratory working space). Niskin and Go-Flo bottles are commonly used for sampling the seawater column; they are designed to minimize contamination and they can pass through the air/sea interface closed. This avoids contamination from the organic-rich, microlayer on the ocean surface where surface-active organic materials are present. Glass and plastic containers (e.g., polysulfone, polycarbonate) that have been thoroughly cleaned and 'aged' (i.e., all leachable components removed by soaking in carbon-free water) are used as temporary storage bottles.

### Sample Treatment and Preservation

Filtration should be carried out immediately after sample collection. This is to minimize biological processes taking place in the sample, which may result in either a net increase (i.e., release from any

organisms present) or decrease of DOC (i.e., microbial consumption). Particulate organic carbon (POC) and the majority of organisms present in the sample can be removed by filtration; pore sizes commonly used range from  $0.2$  to  $0.7\ \mu\text{m}$ . Contamination by carbon leaching from the filter may be significant and should be removed by thorough cleaning. Glass fiber filters (GFFs) are the preferred filter media ( $0.7\ \mu\text{m}$ ; Whatman) as they are robust and are easily cleaned in a furnace by combustion at high temperatures (e.g.,  $450^\circ\text{C}$  for  $>4\text{ h}$ ). Negligible contamination from GFF filters has been observed, although their pore size allows passage of some particles (e.g., bacteria and viruses). However, the fraction of POC in the filtrate is generally negligible compared to typical DOC concentrations. Alternative filters with a smaller pore size ( $0.2\ \mu\text{m}$ ) include polycarbonate and polysulfone filters, although these can significantly contaminate the sample by leaching of carbon. Rapid clogging may present a problem when filtering highly productive waters, reducing the effective pore size of the filter, and increasing the back-pressure possibly causing DOC to leach into the sample via cell lysis. In oligotrophic waters, where the particle loading is minimal ( $<1\%$  of total organic carbon, TOC) the filtration step may be omitted.

When samples need to be preserved, acidification combined with freezing is the chosen option. Sample acidification to pH 2–3 is necessary to (1) remove dissolved inorganic carbon (DIC), and (2) to arrest biological processes from occurring. Mercuric chloride had been used until it was suggested that it might deactivate the catalyst in the HTCO process. High-purity orthophosphoric acid ( $\text{H}_3\text{PO}_4$ ) is the preferred choice of acid as it is commercially available and does not contribute significantly to the procedural blank. Several possible interferences can arise from acidification; these include the production of volatile products from the hydrolysis of organic matter and the precipitation of macromolecules. However, no studies on these effects have been reported to date. Once acidified, samples can be stored frozen at  $-20^\circ\text{C}$  or in flame-sealed airtight glass ampoules refrigerated at  $4^\circ\text{C}$ .

### Decarbonation

DIC concentration is at least an order of magnitude greater than DOC concentration in seawater and therefore has to be removed before analysis. This is achieved by subsequent purging of the acidified sample with  $\text{CO}_2$ -free gas (e.g., ultrahigh purity (UHP) nitrogen, oxygen, or helium). Loss of volatile organic carbon during purging is likely to be minor, amounting to  $<1\%$  of total organic carbon. The efficiency

of DIC removal will depend upon gas flow rate, duration, sample volume, and sample pH. For small sample volumes ( $<40$  ml) a gas flow rate of  $100\text{--}120\text{ ml min}^{-1}$  for 6–8 min should be adequate. Coagulation of colloidal matter on the bubbles, flocculation, and precipitation processes during purging could result in heterogeneity of the sample and therefore mixing of the sample prior to injection may be necessary.

### Analysis of DOC by HTCO

Direct injection (typically  $200\text{ }\mu\text{l}$  aliquot volumes) HTCO systems operate on the principle of oxidation of organic carbon compounds in aqueous samples and subsequent quantification of the generated  $\text{CO}_2$  by IRGA. Injection is carried out onto an oxidation column filled with catalyst (e.g., platinum on aluminum oxide, cobalt oxide, copper oxide) at a temperature between  $600^\circ\text{C}$  and  $900^\circ\text{C}$  in a carbon-free, pure gas atmosphere (e.g., oxygen, nitrogen). The organic matter present in the sample is oxidized on the catalyst to  $\text{CO}_2$ . The stream of gas products is dried using a dehumidifier (e.g., electronic dehumidifier, magnesium perchlorate) and purified by means of gas scrubbers (e.g., halogen scrubber) and particle filters before final determination with the IRGA. The signal (voltage) from the IRGA is recorded using a data collection/integration system; the peak area is used to calculate the amount of carbon present in the sample. The system is calibrated using a carbon compound (e.g., potassium hydrogenphthalate, sulfathiazole, sodium hydrogencarbonate, sucrose) diluted

in low-carbon water (LCW). The main components of a HTCO system are highlighted in Figure 1.

### Analytical Challenges Associated with HTCO

Although current HTCO techniques can provide highly precise ( $\pm 1\text{--}2\%$  RSD) data (Table 1), some analytical problems may be encountered. Quantitatively, the most significant sources of error are: (1) mechanical effects associated with HTCO techniques (e.g., sample injection, salt deposition, memory effects), (2) the estimation of the system blank (i.e., contaminant carbon emissions from the catalyst and components of the analytical system), and (3) the oxidation efficiency.

### Mechanical Effects

Automated injection systems are less labor intensive and less susceptible to contamination leading to improved repeatability.

As the sample is injected onto the catalyst at high temperatures, expansion occurs causing a pressure pulse higher than the void space of the column. A cold zone at the headspace of the column results, and this leads to the deposition of salt/carbonaceous residues. The salt deposits may block the column head resulting in an incomplete combustion of the organic compounds and/or a memory effect (i.e., carryover between samples). Flushing with copious amounts of LCW through the system can remove salt residues but replacement of catalyst may be necessary after extensive salt 'degradation'.

### System Blank

In order to accurately measure DOC in seawater, it is necessary to quantify the system blank. The catalyst is considered to be the major source of carbon contamination in the system. Carbon contamination can vary between catalysts (e.g., alumina has a higher adsorption capacity for CO<sub>2</sub> than silica) and there is lack of a completely carbon-free water to calculate the carbon contamination from the system components alone.

It is possible with some commercially available TOC analyzers (e.g., Shimadzu TOC-5000) to condition the catalyst and effectively measure the system blank by running a ‘closed-loop blank-check’ program. This program involves the injection of LCW onto the catalyst where it is combusted and collected downstream as pyrolyzed water (i.e., theoretically carbon-free water). The latter is subsequently reinjected to determine the system blank. An alternative correction approach, when such a program is not available, is the subtraction of an average of LCW injections (i.e., system plus water blank) from the sample measurements. However, this blank-correction method may result in an underestimation of the DOC concentration in seawater samples. The use of reference materials (see below) is important for system accuracy and reliability. Blank concentrations typically quoted in the literature are  $<10 \mu\text{mol l}^{-1}\text{C}$  after rigorous cleaning/conditioning of the catalyst. A common protocol for blank estimation and correction has yet to be accepted; therefore, reporting the applied method of blank estimations is crucial.

### Oxidation Efficiency

Oxidation efficiency of the HTCO technique will be a function of the refractivity of the natural organic material dissolved in the analyzed sample. Since the chemical character of dissolved organic matter is largely unknown, it is not possible to be sure that any standards chosen will be representative of naturally occurring organic matter. Nevertheless, efforts to evaluate the oxidation efficiency of HTCO have been made using various model compounds with different degrees of refractivity (i.e., caffeine, antipyrine, thiourea, graphite, diamond). Recent studies on percentage recovery for current HTCO techniques quote  $>94\%$ ; however, a direct comparison between techniques is not often possible due to the use of different catalysts and reference compounds. A summary of analytical figures of merit from recent studies on the oxidation efficiency of HTCO systems is given in Table 1. Some studies have shown that complete oxidation can be achieved without a catalyst (e.g., using pure quartz beads) and using a carrier gas that does not include oxygen, bringing into question the

combustion mechanism occurring in HTCO systems. It is recommended that a set of compounds of different refractivity, each at the predicted sample range of concentrations, should be injected to evaluate the oxidation efficiency. Oxidation efficiency should be determined on each day of analysis until constant percentage recovery patterns are established, after which periodic assessment is sufficient.

### Analytical Performance

Published literature on measurements of DOC by HTCO has shown that, currently, the most commonly adopted standard material used for analytical accuracy is potassium hydrogen phthalate (KHP). A summary of analytical performance criteria for several HTCO systems using predominantly KHP is provided in Table 1.

### Certified Reference Materials

Analyses of DOC in seawater samples by HTCO techniques can display unreliability on a daily basis. Certified reference materials (CRMs) are therefore essential for checking the performance of the HTCO techniques. Although, official CRMs are not currently available, in the last decade, the international community has seen several efforts to produce reference materials for DOC measurements. Interlaboratory exercises are underway to provide ‘consensus reference materials’ (i.e., samples assigned an agreed concentration by several laboratories) to the analytical community for increased accuracy. Achieving good agreement between analysts (i.e., values that are within the expected concentrations  $\pm 1\text{--}2\%$  RSD) is crucial for the rigorous comparison and interpretation of different environmental datasets.

Accurate measurements of DOC coupled with techniques such as tangential flow ultrafiltration for size distribution of DOM, nuclear magnetic resonance spectroscopy, soft-ionization mass spectrometry, and elemental ratios will allow marine chemists to define major compositional changes of DOM in the marine environment. Such knowledge can provide an understanding of the mechanisms of biogeochemical cycles, as well as the ability to calculate DOM fluxes accurately on regional and global scales within marine systems and at their interface.

### Introduction

The oceans cover about two-thirds of the globe and represent most of the the biggest water reservoirs on earth. However, because humans live only on the fringes of the oceans, they are less studied, less well understood, and less perturbed from their pristine state than the terrestrial environment. The chemical analysis of the seawater itself represents a major analytical challenge that for many elements is only now beginning to be successfully accomplished. These problems are in part oceanographic, reflecting the size and complexity of the ocean system, and in part chemical, and these latter are the focus of this brief article. This article covers the inorganic analysis of seawater, excluding radioactive species, in both deep-sea and coastal waters and excludes consideration of gaseous species.

The dissolved ion chemistry of seawater is dominated by eight ions all present at millimolar concentrations or more, with sodium and chloride as the overwhelmingly dominant ions (Table 1). The ratio of these eight ions one to another is very constant in ocean waters because the long residence time of these ions ( $\sim 10^6$  years) allows for complete mixing of the waters at fast rates compared to internal mixing,

input, and removal processes. Seawater is also strongly buffered by the hydrogencarbonate–carbonate–carbon dioxide system at about pH 8. In addition to these dissolved ions, seawater contains both biological and abiological particulate matter, dissolved gases, and dissolved organic matter. The analysis of these phases is the subject of separate articles. While these so-called major ions of seawater are present at concentrations of  $10^{-3} \text{ mol l}^{-1}$  or greater, every stable element in the periodic table is probably present, though at much lower concentrations ranging from  $10^{-6}$  down to  $10^{-12} \text{ mol l}^{-1}$  or possibly lower still. Many of these ions display important variations of concentrations in space and time that are of great interest to marine scientists both in terms of understanding the chemistry of the oceans and in terms of monitoring environmental quality. The challenge for chemical analysis of seawater is therefore to often measure the concentrations of ions (or complexes) present at submicromolar concentrations in the presence of millimolar concentrations of the major ions.

### Sampling

The first task is to collect a water sample that represents the area from which it was collected. There are numerous problems of collecting representative samples associated with the heterogeneity of the biogeochemical processes in the oceans. For the analyst the concerns are related to sample integrity. The collection of surface water samples from a small boat can be relatively straightforward, with the sample storage bottle being opened under water and filled by someone leaning over the front of the boat, taking great care to avoid contaminating the sample with surface films on the water or emissions from the boat. On larger vessels, devices capable of continuously pumping uncontaminated surface water samples into the ship's laboratories are now available. The task is more difficult when considering the collection of samples from water depths of several kilometers. Many early sampling campaigns used inappropriate collection systems, resulting in the

### Introduction

The oceans cover about two-thirds of the globe and represent most of the the biggest water reservoirs on earth. However, because humans live only on the fringes of the oceans, they are less studied, less well understood, and less perturbed from their pristine state than the terrestrial environment. The chemical analysis of the seawater itself represents a major analytical challenge that for many elements is only now beginning to be successfully accomplished. These problems are in part oceanographic, reflecting the size and complexity of the ocean system, and in part chemical, and these latter are the focus of this brief article. This article covers the inorganic analysis of seawater, excluding radioactive species, in both deep-sea and coastal waters and excludes consideration of gaseous species.

The dissolved ion chemistry of seawater is dominated by eight ions all present at millimolar concentrations or more, with sodium and chloride as the overwhelmingly dominant ions (Table 1). The ratio of these eight ions one to another is very constant in ocean waters because the long residence time of these ions ( $\sim 10^6$  years) allows for complete mixing of the waters at fast rates compared to internal mixing,

input, and removal processes. Seawater is also strongly buffered by the hydrogencarbonate–carbonate–carbon dioxide system at about pH 8. In addition to these dissolved ions, seawater contains both biological and abiological particulate matter, dissolved gases, and dissolved organic matter. The analysis of these phases is the subject of separate articles. While these so-called major ions of seawater are present at concentrations of  $10^{-3} \text{ mol l}^{-1}$  or greater, every stable element in the periodic table is probably present, though at much lower concentrations ranging from  $10^{-6}$  down to  $10^{-12} \text{ mol l}^{-1}$  or possibly lower still. Many of these ions display important variations of concentrations in space and time that are of great interest to marine scientists both in terms of understanding the chemistry of the oceans and in terms of monitoring environmental quality. The challenge for chemical analysis of seawater is therefore to often measure the concentrations of ions (or complexes) present at submicromolar concentrations in the presence of millimolar concentrations of the major ions.

### Sampling

The first task is to collect a water sample that represents the area from which it was collected. There are numerous problems of collecting representative samples associated with the heterogeneity of the biogeochemical processes in the oceans. For the analyst the concerns are related to sample integrity. The collection of surface water samples from a small boat can be relatively straightforward, with the sample storage bottle being opened under water and filled by someone leaning over the front of the boat, taking great care to avoid contaminating the sample with surface films on the water or emissions from the boat. On larger vessels, devices capable of continuously pumping uncontaminated surface water samples into the ship's laboratories are now available. The task is more difficult when considering the collection of samples from water depths of several kilometers. Many early sampling campaigns used inappropriate collection systems, resulting in the

reporting of erroneously high concentrations owing to contamination of the samples. Since the mid-1970s, sampling systems based on nonmetallic or high-grade stainless-steel cables and all-plastic water samplers designed to open below the surface of the water and to then be closed on command at depth in the ocean have become the norm, particularly for the measurement of trace metals at nanomolar concentrations. In deep ocean environments requirements for strength may demand the use of metal sampling frames to support plastic sampling bottles and these may be either of high-grade stainless steel or possibly of a more expensive metal that is less likely to corrode, such as titanium. This has the additional advantage that titanium is not usually an analyte of great interest whereas iron is, so the possibility of contamination from a titanium frame is of less importance than from a stainless steel one.

Once the samples are returned to the sampling platform it is necessary to minimize the risk of contamination from the atmosphere on the research boat. While careful discharge of the samples into sample storage bottles on deck is often satisfactory, the ideal strategy is to carry out all sample handling (at least for trace metals) in specially designed laboratories with positive pressure of filtered air to minimize the risk of contamination. The extent to which these precautions are necessary varies depending on the analyte of interest, its contamination potential, and its ambient concentration. Furthermore, the procedures for one analyte may be incompatible with another, and careful planning and preparation are essential prerequisites for successful sampling. Some marine waters are devoid of oxygen (e.g., deeper parts of the Black Sea) and particular care is necessary in order to sample such waters without introducing oxidation artifacts. In such cases it is usually necessary to conduct all sample processing prior to sample stabilization under an inert (nitrogen) atmosphere (see Figure 1).

## Sample Treatment and Storage

In deep ocean waters particulate matter concentrations are very small and it is usually unnecessary to filter samples. However, in surface waters and coastal areas, particulate matter concentrations are much higher and filtration to remove particulate matter is usually needed. This ideally serves four purposes:

- (1) To remove living organisms whose subsequent growth or death may compromise the sample integrity.
- (2) To remove particulate matter that may interfere with the storage or subsequent analysis of the sample.

**Figure 1** Rosette sampling system containing niskin bottles for water column sampling. (Photograph: Chris Lowe.)

- (3) To allow a rigorous definition of solid and dissolved phases.
- (4) To allow separate analysis of the particulate phase to provide additional geochemical data for research and environmental monitoring.

Unfortunately, no simple filtration procedure can unambiguously achieve all these results and it is therefore normal practice to filter samples through 0.45  $\mu\text{m}$  pore-size filters and define everything in the filtrate as dissolved, although it is recognized that this will include colloidal material. The role of colloids is an important area of current geochemical research and the separate analysis of this phase is therefore sometimes considered. Many analyses cannot be conducted at sea since they require complex instrumentation, and storage is therefore necessary. After filtration further measures to stabilize samples for storage to avoid changes in concentrations as a result of biological processes or adsorption/desorption processes on the sample container walls are needed. As with sampling, careful planning and evaluation are necessary to ensure satisfactory storage, since a suitable storage procedure for one analyte may not be appropriate for another. There are a

number of strategies available to try to stabilize the samples depending on the most likely storage problems. Thus, for metal analysis, adsorption to the walls is of particular concern and samples are routinely acidified to pH  $\sim$ 2, which serves to saturate potential adsorption sites on the container and stabilize ions in solution. However, such acidification will inevitably perturb the chemical speciation of the ions if this is of interest. In the case of nutrient ions (see later), biological processes are of primary concern and two strategies are routinely used: (1) deep freezing the samples to slow all reactions and prevent migration, (2) adding a poison such as mercury(II) chloride to prevent biological activity. In some cases a combination of these approaches is used. However, storage of samples for nutrient analysis from surface waters where concentrations are extremely low and biological cycling is particularly intense is plagued with difficulties and no universally accepted storage procedure is available.

The last point to be noted under sample storage is that it is essential that sample storage be done in containers that have been rigorously precleaned to avoid the leaching of ions from the walls contaminating the samples. This is particularly of concern for trace metals and rigorous acid cleaning of sample bottles is usually necessary. For most analytes, plastic containers (e.g., polytetrafluoroethylene (PTFE), low-density polyethylene (LPDE)) are preferred, but, for mercury in particular, glass is preferred to avoid the possible loss of volatile species.

## Major Ions

Since the major ions are present in seawater at constant ratios to one another, it is normally not necessary to measure the concentrations of all the ions since the concentration of one will allow the prediction of the others. Thus, chloride has traditionally been measured using a silver nitrate titration, and from this the salinity (i.e., total dissolved salt concentrations) can be derived. Now, however, conductivity is the routinely measured parameter and this is converted to salinity by a relationship agreed internationally with interlaboratory agreement ensured by the distribution of standard seawater samples for instrumental calibration. The use of modern inductively coupled conductivity measurements with careful temperature controls allows salinities to be determined with accuracy and precisions of the order of  $\pm 0.01\%$  or better.

If the measurement of individual major ions is required, the metals can readily be determined by atomic absorption spectrometry (AAS) or inductively coupled plasma-atomic emission spectrometry

(ICP-AES) after suitable dilution and with appropriate matrix matching and background correction. It is possible to determine chloride and bromide by classic silver nitrate titration and sulfate by barium chloride precipitation, but the analytical method of choice would now probably be ion chromatography with careful control of eluent concentrations and instrument sensitivity to avoid the very large chloride peak overlapping with the other anions of interest. Ion chromatography can also be used to measure fluoride, iodate, and iodide, though electrochemical and spectrophotometric techniques are more generally used. Hydrogencarbonate (bicarbonate) is rarely determined exclusively; rather the alkalinity is measured traditionally by titration with acid to pH 4, thus determining the sum of the bicarbonate, carbonate, and the small amounts of borate and phosphate present. The alkalinity of the surface ocean and related components of the  $\text{CO}_2\text{--HCO}_3^- \text{--CO}_3^{2-}$  system in the ocean vary with space and time. Current concerns over the rate of carbon dioxide uptake by the oceans as a factor in the greenhouse effect have led to the development of extremely accurate and precise measurements of the various components of the carbon dioxide system.

## Nutrients

Many of the ions in seawater are essential for the growth of phytoplankton, the microscopic floating photosynthetic algae that form the base of the marine food web. However, many of these ions are present in relatively high concentrations (e.g.,  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ) or in the case of some metals are required only in very small amounts. Thus, it has traditionally been accepted that only the elements nitrogen, phosphorus, and silicon are required in relatively large amounts and yet they are present at rather low concentrations and hence may limit the rates of phytoplankton growth in seawater. This view is now being challenged and it may be that some trace metals can also limit algal growth; nevertheless, the traditional view of the importance of these elements coupled with concern over eutrophication problems in coastal waters, arising from excessive inputs of these elements, justifies a separate treatment for them. Their biochemical roles are rather different from one another, with nitrogen and phosphorus being used for organic matter and silicon being used for skeleton construction by some species of algae, but all are generally called nutrients.

Dissolved inorganic phosphorus (DIP) is present in seawater as the various dissociation products of

phosphoric acid, and silicon is present mainly as the undissociated silicic acid, though the analytical methods in routine use for these ions measure all the inorganic forms of the elements. Nitrogen gas in seawater is unavailable to most, but not all marine algae, so the inorganic species of interest are nitrate (the thermodynamically stable form under oxygenated conditions), nitrite, and ammonium. In addition to the inorganic forms of these nutrients, organic nitrogen and phosphorus species are known to occur in seawater. The analyses of the individual organic compounds are discussed elsewhere, but it is common practice in some laboratories to determine total dissolved organic nitrogen and phosphorus by measuring the concentrations of DIP, nitrate, ammonium, and nitrite before and after strong chemical or photochemical oxidation and considering the differences between the two measurements to represent organic phosphorus and nitrogen. The efficiency of these oxidation procedures has recently been evaluated and there is now no doubt that there are significant levels of dissolved organic nitrogen and phosphorus in surface water.

Colorimetric methods for the determination of DIP, nitrate, nitrite, ammonium, and silicate are well established, with both manual and automatic procedures well understood and able to provide adequate sensitivity for most purposes. These methods can readily be used at sea and in the future probably *in situ*. International intercalibration exercises have shown that many laboratories now have the analytical expertise to measure nutrient concentrations at ambient levels, but this is not true of all laboratories and the analysis still requires careful analytical procedures that recognize the importance of contamination control, blank correction, and the complications arising from the saltwater matrix. Although there have been a number of such intercalibration studies, there is no widely available standard reference material for nutrient analysis at present.

In surface waters nutrient concentrations are often depleted below the detection limits of the routine colorimetric methods even when using the longest-pathlength spectrophotometer cells routinely available (10 cm). The accurate measurement of concentrations of these nutrients at nanomolar concentrations is now an important analytical goal. Therefore, in recent years, new methods for the analysis of nitrate and ammonium with lower detection limits have been developed based on chemiluminescence for nitrate, fluorescence or concentration of the standard colorimetric complex for ammonium, and preconcentration for DIP. Recently, the development of wave guides has opened up the possibility of using cell

lengths of a meter or more which allow great improvements in the sensitivity of nutrient methods using conventional colorimetric procedures.

## Trace Metals

Over recent years the main analytical challenge in inorganic marine chemistry has been the measurement of the trace metals, i.e., metals and metalloids other than those major ions in seawater. The concentrations of trace metals are universally low ( $10^{-9} \text{ mol l}^{-1}$  or less) and their determination in a seawater matrix represents a major challenge. However, as noted earlier, it was the collection of samples without contamination that prevented, until recently, the generation of oceanic profiles of trace metals that could be readily interpreted in terms of well-understood oceanographic processes. Standard reference materials have now been prepared to improve interlaboratory comparability, and a number of international intercomparison exercises have demonstrated good agreement between experienced laboratories. Furthermore, it has become clear that in deep ocean waters, trace metal concentrations show little short-term variation and show variation in concentration with depth and between ocean basins that can be explained by well-understand biogeochemical and oceanographic processes. This allows repeat sampling at locations to be used as a rigorous test of sampling and analytical procedures. Indeed, the International Oceanographic Commission (IOC) has begun a process of establishing the baseline concentrations of some trace metals in the major ocean basins of the world. Once the extremely rigorous protocols necessary for such sampling were put into force, it became possible to focus on the chemical analysis of these low concentrations.

A wide variety of different methods of analysis have been applied to different trace metals in seawater. All these documents are beyond the scope of this article and the reader is referred to Further Reading. In general, the methods fall into two groups: those that can be used without preconcentration and those that do require such a procedure. In the first group are spectrophotometric, chemiluminescence, and fluorimetric procedures, electrochemical methods, and some ICP-AES and inductively coupled plasma mass spectrometry (ICP-MS) methods. In the latter group, involving preconcentration, a variety of concentration methods have been used followed by AAS, gas chromatography, mass spectrometry, and neutron activation methods, or indeed any of the direct analysis procedures. These methods will now be briefly discussed.

## Techniques

### Electrochemical Methods

Anodic stripping voltammetry has been widely used as an analytical procedure because it has the sensitivity to measure a number of metals of interest (zinc, cadmium, copper, and lead) directly in seawater. Furthermore, the method can be sensitive to the chemical speciation of the metal. Thus, if the metals are present as strong and stable organic complexes, as is now known to be the case, for example, for a number of metals including copper, the labile (weakly complexed) metal can be determined directly and the total metal after suitable pretreatment. Recent advances mean that stability constants can also be determined for these strong complexes. The instrumentation for these analyses is portable and robust, thus allowing determinations to be made at sea, minimizing storage artifacts. In the future *in situ* electrochemical methods will become practical. The applicability of electrochemical methods has been limited to a few metals of appropriate reduction potentials, but more recently techniques involving complexation of a metal and the electroplating of this complex using cathodic stripping voltammetry have extended the range of metals that can be measured and the sensitivity of analysis for other metals.

### Spectrophotometry, Chemiluminescence, and Fluorescence Methods

There are a number of colorimetric methods available for the measurement of trace metals in seawater, though, in general, few have the sensitivity to measure the low ambient concentrations. However, in some environments the ferrozine method for iron and the formaldoxine method for manganese have been used successfully. Recently, these methods have been adapted to allow *in situ* measurements of iron and manganese in hydrothermal plumes at mid-ocean ridges.

Fluorimetry, in principle, offers improved sensitivity, but rather few methods have been developed using this approach, with the notable exception of the lumogallion method for aluminum, which has been widely adopted with considerable success. Chemiluminescence methods have also been described for some metals, most notably for iron, a species of great current interest. Chemiluminescence methods have now been used on remotely operated vehicles operating in the deep sea. At ambient concentrations chemiluminescent measurement of iron requires a preconcentration step which can be setup inline for automatic operation.

### Inductively Coupled Plasma Methods and Electrothermal Atomic Absorption Spectrometry

A disadvantage of direct measurements of trace metals in seawater by atomic spectrometric methods is the very large interferences arising from the major ion matrix. The very high temperatures of plasma systems can act to reduce these interferences and, for barium at least, direct measurement of seawater concentrations by ICP-AES has been reported even at open-ocean concentrations. ICP-AES lacks the sensitivity to measure most other trace metals directly at oceanic concentrations, but may offer possibilities for contaminated estuarine waters. ICP-MS offers much greater sensitivity, though various interference problems limit the range of metals to which this technique can be applied. However, direct measurements of uranium and barium have now been reported using ICP-MS after dilution to minimize matrix effects. The speed and multielement capability of ICP-MS obviously offers real advantages coupled to the possibility of measuring isotopic ratios. Against these advantages must be set the disadvantages of cost, complexity, and the fact that the systems cannot be used at sea.

Direct measurements of several trace metals by electrothermal atomic absorption spectrometry (ETAAS) have been reported. In general, sensitivities are inadequate for open-ocean waters, though in more metal-enriched environments (e.g., coastal waters and sediment pore waters) such analysis is possible; careful corrections for the large and complex salt effects are necessary. The interferences can be minimized by the use of appropriate chemical modifiers, platforms in the graphite tubes, and sophisticated background correction schemes such as Zeeman.

### Preconcentration Procedures

Probably the most widely used procedure for trace metal analysis of seawater over the last 20 years has been preconcentration followed by ETAAS because of the wide availability, good sensitivity, and large range of elements that can be measured by this method. Preconcentration procedures have in general been one of three types. First, co-precipitation, with iron(III) 'hydroxide' or cobalt pyrrolidinedithiocarbamate, being the most widely used co-precipitants. Second, complexation followed by solvent extraction with a number of different complexants, of which dithiocarbamates, 8-quinolinol, and dithizone are particularly popular, and with extraction into a range of solvents. The third approach is extraction on to a chelating column (usually Chelex-100 but recently also other complexants such

as ethylenediaminetetraacetic acid or 8-quinolinol immobilized on a silica gel). These approaches all effect a substantial concentration (10–1000-fold), and separate the metals of interest from the bulk matrix, allowing measurement by ETAAS with minimal interferences. The extraction methods are generally efficient, but extraction is pH dependent and careful validation of a technique is always necessary prior to its use. Most methods will extract several metals. In some instances, the extraction techniques can be used to estimate the speciation of metals in seawater by analyzing samples directly without acidification and after acidification. The difference between the results of the two approaches yields a metal fraction only available after acidification has destroyed complexes. While ETAAS has proved a popular method for analysis of these metals, other techniques have been used for quantification including instrumental neutron activation, thermal ionization mass spectrometry, ICP-AES, and ICP-MS. The mass spectrometric techniques offer the advantage of measuring different isotopes of the metal, a property that has been effectively exploited for lead. The ICP techniques offer the option of simultaneous multi-element analysis of a sample with real advantages in rates of sample analysis. Measurement of iron in seawater by isotope dilution ICP-MS with co-precipitation preconcentration has recently been reported in which the coprecipitant is magnesium hydroxide from seawater itself, offering a simple, low blank procedure.

For some metals including arsenic, selenium, and tin, hydride-generation techniques coupled to atomic absorption instrumentation offer sensitive methods with minimum interference from seawater. Similarly for mercury, cold vapor techniques, usually coupled to gold amalgam as a preconcentration stage, offer suitable sensitivity for measurements in seawater. For all of these metalloids strong organic complexes can be formed in seawater, of which methylmercury and tributyltin complexes have received particular attention because of their high toxicity and tendency to bioaccumulation. While these organic complexes can be estimated by measurements before and after destruction of the organic complexes, such difference techniques are of very limited application if the organic complex forms only a small component of the total element pool. Direct methods of measuring both methylmercury and tributyltin have therefore been developed based on selective volatilization and detection of the organic species.

One last group of techniques that have been developed for trace metals involves complexation of the metal by compounds containing halogens, with subsequent extraction and analysis of these

complexes by electron-capture gas chromatography. The excellent sensitivity of this detection system makes these methods suitable for determination of several trace metals in seawater, limited only by the availability of suitable complexing agents that are element specific or can be separated out by chromatography. These methods can be made species specific, for example, allowing selenium(IV) and (VI) species to be analyzed separately. A further advantage is that gas chromatography is usually sufficiently robust to be used at sea.

### Introduction

Industrial effluents result from various types of industrial processes and disposal practices, and may contain pollutants at levels that could affect the quality of receiving waters, as well as the aquatic ecosystem (Table 1). The emission of industrial pollutants in liquid effluents has to comply with stringent regulatory requirements and guidelines, in which chemicals listed should not exceed a given concentration. On the other hand, a chemical company may release a large number of different chemicals, which are not considered by regulatory requirements

and in many cases are unknown. These compounds may be the final products, precursors, or intermediates of the process, or impurities and by-products. One of the distinguishing characteristics of effluents of industrial origin, as compared to municipal wastewaters, is that often they may contain a mixture of different and very toxic substances. Approved analytical methods exist for compliance monitoring of conventional pollutants in industrial effluents; however, because of the complexity of the sample matrix, several analytical methods are required to determine polar and nonpolar organic compounds and new emerging pollutants that may impact water quality. As a consequence, modifications in instrumentation, sampling, and sample preparation techniques have become essential to comply with the regulatory water standards, as well as to achieve a faster speed of analysis.

### General Chemical Analysis of Industrial Effluents

This section provides a brief overview of some of the most important tests that are performed on wastewaters.

#### pH, Hardness, Alkalinity, and Conductivity

General measures of the ionic characteristics of water are pH, hardness, alkalinity, and conductivity. There are several others that could be added to this group, such as redox potential and salinity; however, these

four are the most important. Generally, pH is measured using a pH meter consisting of a potentiometer, a glass electrode, a reference electrode, and a temperature-compensating device. A circuit is completed through the potentiometer when the electrodes are submersed. For alkalinity the samples are titrated electrometrically with hydrochloric acid or sulfuric acid to an endpoint of pH 4.5, and specific conductance is measured by use of a self-contained conductivity meter.

### **Total Organic Carbon**

Total organic carbon (TOC) analysis is based on the principle that carbon in an aqueous sample is converted to carbon dioxide by catalytic combustion or wet chemical oxidation. The carbon dioxide formed is measured directly by an infrared detector or converted to methane and measured by a flame ionization detector. The amount of carbon dioxide or methane is directly proportional to the concentration of carbonaceous material in the sample. Inorganic carbon is removed by acidification of the sample prior to analysis.

### **Chemical Oxygen Demand**

The chemical oxygen demand (COD) test gives a measure of the total organic content in terms of oxygen by oxidizing all biodegradable and nonbiodegradable organic materials with a strong oxidizing agent such as potassium dichromate. Silver sulfate is used as a catalyst, and mercury(II) sulfate is added to remove chloride interference. Absorbance is measured spectrophotometrically at 600 nm.

### **Biological Oxygen Demand**

The rapid and real-time monitoring of the gross amount of organic matter in municipal and industrial effluents is a major problem for every industry. Amongst all the parameters for which wastewaters are monitored, the organic biodegradable carbon is one of the most important and more frequently used parameters for estimating the level of wastewater pollution. The biological oxygen demand (BOD) test is a bioassay procedure that measures the amount of oxygen consumed by bacteria and other microorganisms from the decomposition of organic matter over a given period of time at a specified temperature. In the classical 5-day BOD test, the sample of wastewater is diluted with well-oxygenated and nutrient-containing water, and microorganisms adapted to the wastewater are introduced. The initial dissolved oxygen concentration is determined, and the sample is stored in darkness at 20°C for 5 days. The difference in oxygen concentration between the beginning and end

of the test period gives the 5-day BOD value. The need for fast, portable, and cost-effective methods for environmental monitoring has stimulated the production of a variety of field analytical tools such as biosensors, which shortened the BOD time analysis from 3–5 days to 5 min.

### **Oil and Grease**

Oil and grease refer to a broad class of organic substances that are recovered from effluent matrices by extraction with a nonpolar solvent under acidic conditions. Oil and grease compounds are substances such as hydrocarbons, vegetable oils, animal fats, waxes, soaps, and greases. Many solvents can dissolve other substances (e.g., sulfur compounds, chlorophyll, etc.). Therefore, oil and grease is operationally defined by the solvent used and the analytical method used to perform the analysis. There are two basic methods used to analyze oil and grease: the gravimetric technique and the infrared method.

### **Ammonia**

Monitoring the nitrogen content is of great importance in many industries for many reasons. In waters and wastewaters the most interesting forms of nitrogen, in order of decreasing oxidation state, are nitrate, nitrite, ammonia, and organic nitrogen. The occurrence of ammonia in wastewaters is primarily attributed to its formation resulting from the reduction of nitrogen-containing organics, deamination of amines, and hydrolysis of urea, and also to its use in water treatment plants for dechlorination. Ammonia may be analyzed after distillation of the wastewater sample over one of the following solutions:

- Boric acid – colorimetric Nesslerization method.
- Boric acid-indicator solution – titrimetric analysis.
- Sulfuric acid – colorimetric phenate method or ammonia electrode method.

The colorimetric Nesslerization method uses alkaline phenol and hypochlorite to react with ammonia to form indophenol blue in an amount proportional to the ammonia concentration. The blue color is intensified with sodium nitroprusside, and the concentration is measured using a calibrated colorimeter. The titration of basic ammonia is accomplished with standard sulfuric acid using a mixed indicator. Determination of ammonia may also be based upon the indophenol reaction adapted to automated gas-segmented continuous flow analysis. Potentiometric determination of ammonia is performed by ion-selective ammonia electrodes.

## Anions

Determination of inorganic ions (nitrate, nitrite, bromide, chloride, fluoride, phosphate, and sulfate) in surface water, ground water, drinking water, and domestic and industrial wastewaters can be determined by ion chromatography. The samples are introduced into an ion chromatograph, where the anions of interest are separated and measured using a system comprising a guard column, an analytical column, a suppressor device, and a conductivity detector. Potentiometric determinations of bromide, chloride, fluoride, and sulfide may be accomplished with ion-selective electrodes. Several methods are available for nitrate and nitrite determinations in wastewaters, including direct ultraviolet spectrophotometry, derivatization with benzoic acid, use of nitrate-selective electrodes, and reduction to nitrite followed by derivatization with sulfanilamide and *N*-1-naphthylethylenediamine dihydrochloride.

## Cyanide

Cyanides are soluble metal salts containing one metal ion, or insoluble complexes containing two metal ions, and the cyanide ion ( $\text{CN}^-$ ). The degree and rate of dissociation of complex cyanides to  $\text{CN}^-$  and HCN depend on several factors, including the nature of the metal, pH of the solution, and dilution. Cyanide in industrial wastewaters may be determined by the following methods:

- colorimetric method;
- silver nitrate titrimetric method;
- ion chromatography; and
- flow injection, ligand exchange, and amperometric detection.

Any cyanide present in the sample is converted to hydrocyanic acid by means of a reflux-distillation operation under acidic conditions, and absorbed in a scrubber containing sodium hydroxide solution. In the colorimetric method, the cyanide is released from cyanide complexes by means of a manual reflux-distillation operation and absorbed in a scrubber containing sodium hydroxide solution. The cyanide ion in the absorbing solution is converted to cyanogen chloride by reactions with chloramine-T, which subsequently reacts with pyridine and barbituric acid to give a red-colored complex. Alternatively, cyanide can be determined by titration using silver nitrate ( $\text{AgNO}_3$ ) with *p*-dimethylaminobenzalrhodanine indicator. Fast detection of cyanide in water and wastewaters may be also accomplished using a flow-injection analysis system, pretreated with ligand-exchange reagents. Cyanide is also quantitated by

means of silver working electrode, silver/silver chloride reference electrode, and platinum/stainless steel counter electrode.

## Total Phenols

The total phenolic compounds (*ortho*- and *meta*-substituted phenols) in an aqueous sample can be determined by a colorimetric method using 4-aminoantipyrine. This reagent reacts with phenolic compounds at pH 8 in the presence of potassium hexacyanoferrate(III) to form a colored antipyrine dye, the absorbance of which is measured at 500 nm. The antipyrine dye may also be extracted from the aqueous solution by chloroform, and the absorbance of the chloroform extract is measured at 460 nm.

## Analysis of Metals in Industrial Effluents

Although many metals are toxic, only some metals including aluminum, antimony, arsenic, beryllium, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, and zinc are considered as priority pollutants in industrial effluents. Metals in general can be analyzed in industrial effluents by the following techniques:

- spectrophotometry;
- atomic absorption spectrometry; and
- atomic emission spectrometry.

Colorimetric techniques are employed to analyze aluminum, arsenic, beryllium, cadmium, chromium(VI) and total, copper, lead, and zinc. Some metals may also be determined by other methods, including gravimetry, redox titration, ion chromatography, ion-selective electrodes, anodic stripping voltammetry (ASV), differential pulse polarography, etc. Mercury can be determined by oxidation, purge and trap, desorption, and cold-vapor atomic fluorescence spectrometry (CVAFS). Mercury is oxidized to  $\text{Hg(II)}$ , and then reduced to the elemental state and purged with nitrogen onto a gold-coated sand trap. The mercury vapor passes through a cell of a cold-vapor atomic fluorescence spectrometer for detection. Determinations of dissolved organic and inorganic divalent mercury ions and compounds can also be accomplished by ASV.

In atomic absorption spectroscopy, a sample is aspirated and atomized in a flame. A light beam from a hollow cathode lamp or an electrodeless discharge lamp is directed through the flame into a monochromator, and onto a detector that measures the amount of absorbed light. Absorption depends upon

the presence of free unexcited ground-state atoms in the flame. Because the wavelength of the light beam is characteristic of only the metal being determined, the light energy absorbed by the flame is a measure of the concentration of that metal in the sample. An atomic absorption spectrometer equipped with a graphite furnace or an electrically heated atomizer instead of the standard burner head gives better sensitivity and much lower detection limit than what is obtained with the flame technique.

Metals can be conveniently determined by inductively coupled plasma-atomic emission spectrometry (ICP-AES). A great advantage of ICP emission spectroscopy as applied to environmental analysis is that several metals can be determined simultaneously by this method. Another advantage is that, unlike atomic absorption spectroscopy, the chemical interferences in this method are very small. Chemical interferences are generally attributed to the formation of molecular compounds (from the atoms) as well as to ionization and thermochemical effects. The application of this technique has been selected for the analysis of toxic elements in drinking, ground, surface, and wastewater, or sludge and leachate from wastes. With ICP-AES, these samples are nebulized and the resulting aerosol transferred to a plasma torch, where it is decomposed, atomized, and ionized whereby the atoms and ions are excited. Each element emits light at characteristic wavelengths and these lines can be used for quantitative analysis after calibration. More recently, a new and more expensive technique, inductively coupled plasma-mass spectrometry (ICP-MS), has been introduced as a routine tool. ICP-MS offers the advantages of ICP-AES and the detection limit advantages of graphite furnace-atomic absorption spectrometry.

## Analysis of Organic Compounds in Industrial Effluents

In recent years, increasing attention has been paid to the detection, identification, and quantitation of trace organics and new emerging pollutants in wastewater samples. Analytical techniques for measuring organic compounds in industrial effluents require four general steps:

1. isolation (extraction and separation) of the target chemicals from sample matrix (drinking water, surface water, wastewaters, etc.);
2. separation and purification of the target chemical from co-extracted, nontarget chemicals (sample cleanup);
3. sample concentration; and

4. identification and quantitation by highly selective and sensitive analytical equipment.

Chromatography is the most widely used technique for the analysis of organic compounds in wastewaters. Gas chromatography (GC) (where the sample must be volatilized) and liquid chromatography (LC) (where the sample can be determined in the liquid state) are the most common. LC is the technique of choice whenever the sample cannot easily be converted to the gas phase. A mass spectrometer should be used wherever possible to identify the compounds more correctly. Although it has a lower sensitivity than other GC detectors, MS is, by far, the best confirmatory test for compound identification.

### Selection of Extraction Methods

Chemical substances and their solubility in water depend on their physicochemical characteristics, such as their molecular weight, boiling point, and polarity (Figure 1). Methods for isolating chemicals from water based on these broad chemical categories are shown in Figure 2.

The two main methods for the isolation of volatile organic compounds (VOCs) from water are:

1. The purge and trap (P&T) method, which separates volatile compounds from the aqueous matrix by passing an inert gas such as helium or nitrogen through the matrix (purging). The target, volatile compounds are desorbed from the aqueous phase to the gas phase (purged) and are then separated from the stream of gas by trapping (adsorbent) filters (e.g., porous polymer beads, activated charcoal, silica gel, etc.). In general, the P&T technique is applied to analyze substances that have boiling points below 200°C and are insoluble or slightly soluble in water.
2. The headspace method, less sensitive compared to the P&T method, in which the sample is placed in a sealed container, such as a vial, and left at a constant temperature until the gas and liquid phases are in equilibrium. The target substances in the gas phase (headspace) are collected by gas tight syringe, and injected into the gas chromatograph-mass spectrometer.

Methods to extract semivolatile compounds (SVOCs) from water include the following.

1. Liquid-liquid extraction (LLE) is the most common method for the isolation of SVOCs and nonvolatile compounds from water samples. It is based on the partitioning of analytes from an aqueous phase to a liquid organic phase. In LLE,

**Figure 2** Chemical separation methods for water samples.

hydrophobic analytes are extracted into an organic phase. The water sample and the solvent are placed in a separatory funnel, shaker flask, or bottle, which is shaken or continuously rotated to increase the contact surface area between the solvent and the sample.

2. Solid-phase extraction (SPE), where water sample analytes are passed through and adsorbed onto a

solid support, and then extracted with a solvent or by thermal desorption. The most popular and rapidly emerging method employs commercially available packed columns, rigid disks, speedisks, or extraction disk cartridges, filled with various phases bonded to a silica gel matrix.

3. Solid-phase microextraction (SPME) is a further modification of the SPE technique. Analytes are

isolated from water by passive isolation. SPME provides a solvent-free approach to SPE based on equilibrium sampling. The extraction medium is a fused silica fiber (coated with polymer phase and bonded to a stainless steel plunger) and a holder that has a form of microliter syringe.

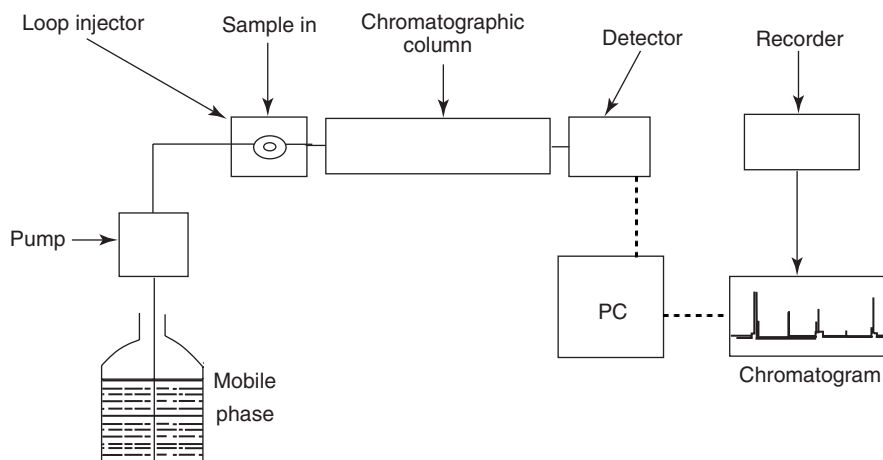

Extracts from industrial effluent samples can be complicated mixtures, with components interfering with GC and LC analysis by giving poor separation because of over separation capacity of a column or by containing compounds that elute at the same time, and interfere with, the target compounds' peaks. The sample extracts may be purified by one or more of the following techniques for different classes of organic compounds.

1. Adsorption chromatography (alumina, silica gel, Florisil): separates analytes of a relatively narrow polarity range away from extraneous, interfering compounds of a different polarity (e.g., organochlorine pesticides, polycyclic aromatic hydrocarbons).
2. Acid-base partitioning: separates acidic or basic organics from neutral organics (e.g., separates chlorophenoxy herbicides from phenols).
3. Gel permeation chromatography: separates high molecular weight, high boiling material from the sample analytes; prevents contamination of GC injection heads and columns (e.g., semivolatile organics and pesticides).
4. Sulfur cleanup: eliminates sulfur from extracts, which may cause chromatographic interference with analytes.
5. Sulfuric acid/permanganate: destroys most organic compounds except polychlorinated biphenyls (PCBs).

## Liquid Chromatography

LC is a sensitive, adaptable, and quantitative analytical technique to separate compounds that are dissolved in solution. **Figure 3** depicts the main components of a modern LC system: (1) a pump with a constant flow control, (2) a high-pressure injection valve, (3) a chromatographic column, (4) a detector, and (5) a data system for measuring peak areas and retention times (**Figure 3**).

LC basically involves the separation of analytes in a mixture by adsorption to a polar or nonpolar support surface or by partition into a stationary liquid phase. These analytes are first dissolved in mobile phase (eluant), and then forced to flow through a chromatographic column (stationary phase) under high pressure. The interaction of the solute with mobile and stationary phases can be manipulated through different choices of both solvents and stationary phases. The stationary phase is defined as the immobile packing material in the column, and which consists of the rigid porous particles, usually silica based, with the specific surface properties. In normal-phase liquid chromatography, a bonded polar surface such as cyano-, diol-, or amino group bound to silica is employed, while the mobile phase is nonpolar. On the other hand, reversed-phase liquid chromatography uses a nonpolar surface such as octadecyl-, octyl-, methyl-, and diphenyl groups bound to silica or polymers, and a polar mobile phase. Water-acetonitrile and water-methanol mixtures are commonly used as polar mobile phase. The most common LC detectors are based on refractive index, ultraviolet/visible, fixed and variable wavelength, diode array, and fluorescence; and the less common but important ones are the conductivity and the evaporative light scattering detectors.

**Figure 3** Diagram of a typical LC setup.

LC has been extensively used in municipal and industrial wastewaters analysis for phenolic compounds, benzidines, diquat, and paraquat, surfactants like alkylphenol and alcohol ethoxylates, agents employed in consumer detergent products like linear alkylbenzene sulfonates (LAS), and other aromatic sulfonates. Recent analytical advances have also been made for priority endocrine disrupting compounds by means LC-MS with the electrospray interface and atmospheric pressure chemical ionization coupled with MS. In the last decade, the significant progress in the development of LC-MS interfacing systems has made unforeseen analytical capabilities available for a wide variety of water pollutants such as LAS, nitro- and chlorophenols, alkylphenol and alcohol ethoxylates, toxins generated during blooms of blue-green algae, cationic surfactants, and antibacterial agent such as dimethylammonium or benzyl alkyl dimethylammonium, organometallic compounds like tributyltin and triphenyltin and related compounds, benzidines and nitrogen-containing pesticides, organophosphorus compounds, chlorinated phenoxyacid compounds and their esters, carbamates, etc.

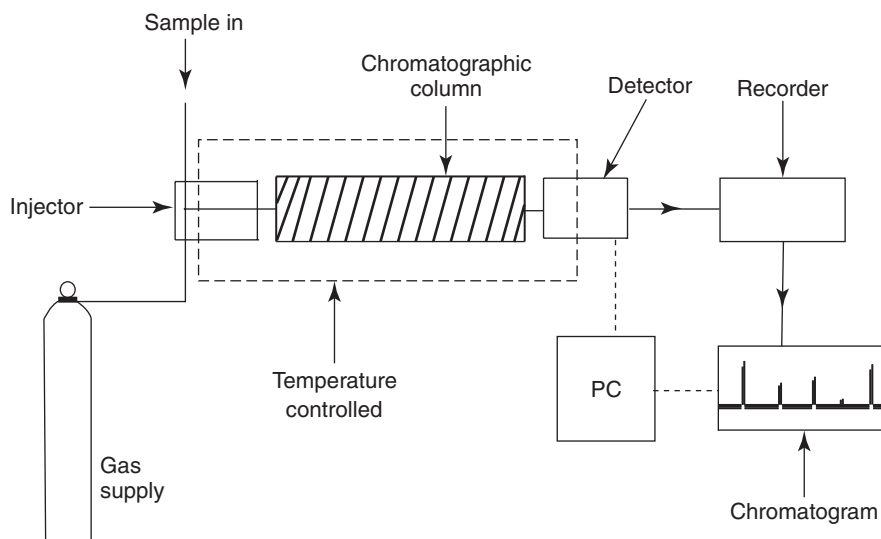

### Gas Chromatography

GC is the most widely used instrumental technique today for quantitative organic chemical analysis for its unparalleled resolving power and sensitivity of detection, combined with relative simplicity of operation. The concept is based on the selective interaction of gaseous or semivolatile compounds (analytes) with the column packing or film as the vaporized

sample is forced through the column by a chemically inert carrier gas (usually nitrogen or helium). Good separation in the shortest period of time is ideal for good GC analysis, and these criteria are related to the liquid phase of columns, film thickness, length, internal diameter, and temperature. Capillary columns are available with many kinds of liquid phases, from nonpolar methylsilicones to highly polar polyethylene glycols. The basic components of a GC system are: (1) a carrier gas cylinder with regulator, (2) a flow controller for the gas, (3) an injection port for introducing the sample, (4) the column, and (5) the detector and the recorder (Figure 4). For GC a number of detectors have been developed; however, the most important for trace organic analysis, besides the mass spectrometer, are:

- flame ionization detector (only detects compounds containing the C-H bond);
- electron capture detector (halogenated hydrocarbons, halogenated pesticide residues, and oxygen-containing groups or nitro groups); and
- nitrogen/phosphorus detector (phosphorus- and nitrogen-containing pesticides, organophosphates, and carbamates).

GC plays a key role in the analysis of VOCs and SVOCs in industrial effluents. VOCs that have boiling points below 200°C can be extracted from water sample matrices using a P&T system. Purged sample components are trapped in a tube containing suitable sorbent materials. When purging is complete, the sorbent tube is heated and backflushed with helium to desorb trapped sample components onto a GC

**Figure 4** Diagram of a typical GC setup.

column. The column separates the analytes, which are identified and quantified using a mass spectrometer. Volatile, water-soluble compounds can be included in this analytical technique by the use of azeotropic distillation or closed-system vacuum distillation. Such compounds include low molecular weight halogenated hydrocarbons, aromatics, ketones, nitriles, acetates, acrylates, ethers, and sulfides. Nonhalogenated VOCs in aqueous samples are introduced into the gas chromatograph using the P&T system, and detection is achieved by a flame ionization detector.

Among semivolatile compounds, organochlorine pesticides are analyzed by GC using single/double fused-silica column (open-tubular and/or capillary columns) with an electron capture detector or an electrolytic conductivity detector. Depending on the nature of interferences and target analytes, a combination of cleanup procedures including alumina, Florisil, silica gel, gel permeation chromatography, and sulfur may be applied prior to instrumental analysis.

PCBs congeners and Aroclor mixtures are also determined either by a single/dual column analysis system with electron capture detectors. Compound identification based on single-column analysis should be confirmed on a second column, or should be supported by a confirmation technique such as GC/MS. Extracts for PCB analysis may undergo a sulfuric acid/potassium permanganate cleanup to remove coeluting organochlorine or organophosphorus pesticides and sulfur cleanup to remove chromatographic interferences due to elemental sulfur.

Herbicides may be determined by specific extraction, esterification, and gas chromatographic conditions. Aqueous samples are extracted with diethyl ether and then esterified with either diazomethane or pentafluorobenzyl bromide. The derivatives are determined by GC with an electron capture detector. Compound identifications should be supported by GC-MS for the qualitative confirmation. Alkaline hydrolysis and subsequent solvent wash removes many chlorinated hydrocarbons and phthalates that might otherwise interfere with the electron capture analysis.

### Gas Chromatography-Mass Spectrometry

GC-MS is the coupling of two analytical techniques into a versatile and probably the best technique to identify a wide array of organic substances in industrial effluents. GC-MS is based on chromatographic separation of the different constituents of the sample on a GC column, and their subsequent analysis and identification by MS. The major components of

the mass selective detector are: an ionization source, mass separator, and ion detector. The two common mass separators commercially available for GC-MS are the quadrupole and the ion trap. As a sample elutes from the GC column, it enters the ionization chamber of the mass spectrometer where the molecules are ionized, typically by electron impact. The mass analyzer scans stepwise through a set range of mass values to evaluate the relative abundance of ions at each mass value. The result is a total ion chromatogram, which is a plot of the total mass eluting from the GC and detected by MS as a function of time. Compounds are identified from the mass spectrum by a computerized comparison of the mass spectra for the sample with spectra library for known compounds.

SVOCs that are soluble in methylene chloride and capable of being eluted, without derivatization, as sharp peaks from a gas chromatographic fused-silica capillary column coated with a slightly polar silicone, can be analyzed by GC/MS. Such compounds include polycyclic aromatic hydrocarbons (PAHs), chlorinated hydrocarbons and pesticides, phthalate esters, organophosphate esters, nitrosamines, haloethers, aldehydes, ethers, ketones, anilines, pyridines, quinolines, nitroaromatic compounds, phenols, and nitrophenols. Detection and quantitative measurements of dioxins (PCDDs) and dibenzofurans (PCDFs) in industrial effluents require the use of high-resolution capillary column gas chromatography/low-resolution mass spectrometry (HRGC/LRMS) techniques. Sample extracts may undergo specified cleanup procedures including back-extraction with acid and/or base, and gel permeation, alumina, silica gel, Florisil, and activated carbon chromatography. LC can be used for further isolation of the 2,3,7,8-isomers or other specific isomers or congeners. Isotope dilution HRGC/HRMS may also be employed for PCDD/PCDFs analysis. This technique involves spiking the aqueous sample with stable isotopically labeled analogs prior to sample extraction.

VOCs can also be determined by isotope dilution GC/MS, where stable isotopically labeled analogs of the compounds of interest are available; otherwise, an internal standard method is used. After purging and trapping, the sample is introduced into a gas chromatograph, and the compounds are separated by the GC and detected by a mass spectrometer. The labeled compounds serve to correct the variability of the analytical technique. Identification of a compound (qualitative analysis) is performed by comparing the GC retention time and the background corrected characteristic spectral masses with those of authentic standards.

## Nomenclature

- 2,3,7,8-Isomers = 2,3,7,8-substituted penta-, hexa-, hepta-, and octachlorinated dibenzo-*p*-dioxins and dibenzofurans.
- 4-Aminoantipyrine ( $C_{11}H_{13}N_3O$ ); Synonyms: aminoantipyrine; ampyrone; 4-amino-1,2-dihydro-1,5-dimethyl-2-phenyl-3*H*-pyrazol-3-one; 4-aminophenazone; 4-amino-2,3-dimethyl-1-phenyl-3-pyrazolin-5-one; 4-amino-1,5-dimethyl-2-phenyl-4-pyrazolin-3-one; 3*H*-pyrazol-3-one; 4-amino-1,2-dihydro-1,5-dimethyl-2-phenyl.
- Acetates = (1) Metallic salts derived from acetic acid by interaction of the metallic oxide, hydroxide, or carbonate with the acid; or the esters derived by interaction of alcohols with acetic acid, which include the common esters of ethyl, propyl, isopropyl, butyl, and amyl acetates. (2) A generic name for cellulose acetate plastics, particularly for fibers thereof. When at least 92% of the hydroxyl groups are acetylated, the term triacetate may be used as the generic name of the fiber. (3) A compound containing the acetate group,  $CH_3COO-$ .
- Acrylates = (def) Different acrylic, styrene acrylic, vinyl acrylic products for applications ranging from cement additives to filters (e.g., acrylic acid esters, metallic salts of acrylic acid).
- Alcohol ethoxylates; (C6–C18) Ethoxylates; Synonyms: ethoxylated alcohol, fatty alcohol ethoxylate, alcohol ethoxylate, polyoxyethylene alcohol ether, polyethylene glycol alcohol ether. Surfactant alcohol ethoxylates and their derivatives are used by the detergent manufacturing industry as active ingredients in industrial and consumer products such as soaps, detergents, and other cleaning products.
- Alkylphenol ethoxylates (APEs) have been widely used as part of industrial processes and as detergents in both industrial and household applications for more than 30 years. Octylphenol ethoxylates and nonylphenol ethoxylates are two of the most common surfactants in the marketplace.
- Amines = Compounds formally derived from ammonia by replacing one, two, or three hydrogen atoms by hydrocarbyl groups, and having the general structures  $RNH_2$  (primary amines),  $R_2NH$  (secondary amines),  $R_3N$  (tertiary amines).
- Anilines = Includes aniline and chloro-, bromo-, and/or nitroanilines (benzene amines).
- Nitroaromatic compounds = Nitrogen-containing organic compounds used worldwide as explosives, pesticides, and as precursors for the manufacture of many products, including dyes, pharmaceuticals, and plastics pathway (e.g., 2,4,6-trinitrotoluene (TNT), 1,3,5-trinitrobenzene (TNB), dinitrotoluene (2,4-DNT, 2,6-DNT), dinitrobenzene (DNB), methyl-*N*,2,4,6-tetranitroaniline, and 2,4,6-trinitrophenol).
- Barbituric acid ( $C_4H_4N_2O_3$ ); Synonym(s): 2,4,6 (1*H*,3*H*,5*H*)-Pyrimidinetrione.
- Benzidines = Benzidine and 3,3'-dichlorobenzidine.
- Carbamates = Insecticides that are derivatives of carbamic acid,  $HOC(O)NH_2$ ; widely used against insects, fungi, and weeds, under several commercial names (e.g., Alicarb, Carbaryl, Propoxur).
- Cationic surfactants = (def) Quaternary ammonium compounds that are major components in industrial and commercial formulations such as cosmetics, textile softeners, and pharmaceuticals (e.g., tetramethyl, tetrapropyl, tetrabutyl, dodecyl, cetyltrimethyl, and myristyltrimethylammonium).
- Chlorinated hydrocarbons = (def) (1) Chemicals containing only chlorine, carbon, and hydrogen. These include a class of persistent, broad-spectrum insecticides that linger in the environment and accumulate in the food chain. Among them are DDT, aldrin, dieldrin, heptachlor, chlordane, lindane, endrin, Mirex, hexachloride, and toxaphene. Other examples include TCE, used as an industrial solvent. (2) Any chlorinated organic compound including chlorinated solvents such as dichloromethane, trichloromethylene, chloroform.
- Chlorinated phenoxyacid compounds = One of the most important classes of chlorinated herbicides used to control agricultural and aquatic weeds (e.g., Dalapon, Dicamba, 2,4-D, MCPA, MCPP, 2,4,5-T, etc.). In these compounds, chloro-substituted benzene rings are attached to lower carboxylic acids via an oxygen atom.
- Dibenzofurans (PCDFs) = (def) Polychlorinated dibenzo-*para*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) are two series of compounds that have a triple-ring structure that consists of two benzene rings connected by a third oxygenated ring. For PCDDs, the benzene rings are connected by a pair of oxygen atoms, whereas in PCDFs they are connected via a single oxygen atom. The number of chlorine atoms can vary between one and eight. PCDDs and PCDFs are not commercially produced but are formed as trace amounts of undesired impurities in the manufacture of other chemicals, such as chlorinated phenols and their derivatives, chlorinated diphenyl ethers, and polychlorinated biphenyls (PCBs). Ongoing or earlier use of pentachlorophenol is considered to be a major source of PCDDs and PCDFs in many industrialized countries. PCDDs and PCDFs are also formed in

combustion processes such as waste incineration and in the production of iron and steel.

- Dioxins (PCDDs) = Dioxin is a generic term used to denote a single compound or mixture of compounds derived from polychlorinated dibenzodioxins. The basic structure of all dioxins consists of two benzene rings joined by two oxygen atoms. There are 75 different polychlorinated dibenzo-*p*-dioxins and 135 dibenzofurans that are classified into groups termed homologs on the basis of the number of chlorine atoms in the molecule.
- Endocrine disrupting compounds = Exogenous agents that interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior (e.g., alkylphenols, alkylphenol polyethoxylates, polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), phthalates, bisphenol-A, polybrominated flame retardants, dioxins, furans, herbicides, pesticides, and steroid hormones).
- Haloethers = Compounds that contain an ether moiety (R–O–R) and halogen atoms attached to the aryl or alkyl groups (e.g., bis(2-chloroethyl) ether; bis(2-chloroethoxy)methane; bis(2-chloroisopropyl) ether; 4-bromophenyl phenyl ether; 4-chlorophenyl phenyl ether).
- Halogenated hydrocarbons = Hydrocarbons containing chlorine, bromine, iodine, fluorine (e.g., chloroform, trichloroethylene, tetrachloroethylene, polychlorinated biphenyls).
- Linear alkylbenzene sulfonates (LAS) = Anionic surfactants with molecules characterized by a hydrophobic (apolar) group and a hydrophilic (polar) group. As a class of chemicals, they are generally mixtures of closely related isomers and homologs. Each molecule contains an aromatic ring sulfonated at the *para* position and attached to either a linear or a branched alkyl chain at any position except the terminal carbons. Chain lengths vary but are predominantly in the range of C10–C14.
- Mixed indicator = Methyl red in ethyl alcohol with methylene blue in ethyl alcohol.
- Nitriles = Compounds having the structure  $RC\equiv N$ ; thus, C-substituted derivatives of hydrocyanic acid; the suffix nitrile denotes the triply bound  $\equiv N$  atom, not the carbon atom attached to it.
- Nitrosamines = Nitroso derivatives of amines in which a nitroso (NO) group is attached to the nitrogen atom of the amine (e.g., *N*-nitrosodimethylamine, *N*-nitrosodiphenylamine, *N*-nitrosodi-*n*-propylamine).
- Organochlorine pesticides = A unique class of pesticides because of their cyclic structure, number of chlorine atoms, and low volatility. They can be classified into four categories: dichlorophenylethanes (e.g., DDT), cyclodienes, chlorinated benzenes (e.g., hexachlorobenzene (HCB)), and cyclohexanes (e.g., hexachlorocyclohexane (HCH)).
- Organometallic compounds = Compounds having bonds between one or more metal atoms and one or more carbon atoms of an organyl group. Organometallic compounds are classified by prefixing the metal with organo group, e.g., organopalladium compounds.
- Organophosphate esters are used in a wide variety of applications including hydraulic fluids, plasticizers, and antiwear additives to hydraulic fluids and engine oils. Some are referred to as 'natural' phosphate esters because the cresols and xylenols used as raw materials are derived from petroleum oil or coal tar. The first commercial trialkyl phosphate esters (TAP) were tricresyl phosphate (TCP) and trixylenyl phosphate (TXP); others are known as 'synthetic' phosphate esters, which are derived from specific synthetic reactions to produce triaryl, trialkyl, and alkylaryl esters.
- Organophosphorus pesticides = Most organophosphorus pesticides are vinyl ester derivatives of phosphates. Four classes of organophosphorus pesticides are in use: phosphates ( $R_1, R_2 = O$ ), ( $R_1 = S, R_2 = O$ ), phosphorothioates ( $R_1 = S, R_2 = O$ ), phosphorothiolothionates ( $R_1, R_2 = S$ ), and phosphonates (with a P–C bond). Examples are Parathion, Diazinon, etc.
- Phthalate are the esters of phthalic acid used as plasticizers of synthetic polymers such as poly(vinyl chloride) and cellulose acetate.
- Polychlorinated biphenyls (PCB or PCBs) are a class of chlorosubstituted biphenyl compounds that were once widely used as additives in transformer oils, lubricating oils, and hydraulic fluids. They are formed by the addition of chlorine ( $Cl_2$ ) to biphenyl ( $C_{12}H_{10}$ ), which is a dual-ring structure comprising two 6-carbon benzene rings linked by a single carbon–carbon bond. The nature of an aromatic ring allows a single attachment to each carbon. This means that there are 10 possible positions for chlorine substitution (replacing the hydrogens in the original biphenyl). PCBs have been used as coolants and lubricants in transformers, capacitors, and other electrical equipment because they do not burn easily and are good insulators.
- Polycyclic aromatic hydrocarbons (PAHs) are a group of over 100 chemicals containing

two or more benzene rings fused together, which are formed during the incomplete burning of coal, oil and gas, garbage, or other organic substances like tobacco or charbroiled meat.

- Quinoline ( $C_9H_7N$ ); Synonyms: 1-azanaphthalene, 1-benzazine, benzo(*b*)pyridine. Quinoline is a hygroscopic, colorless liquid at room temperature, with a penetrating amine-like odor; is a constituent of creosote, coal tar, and certain other products derived from fossil fuels, and it is also produced by combustion of a number of substances including tobacco. It is used as a solvent and a decarboxylation reagent, and as a raw material for manufacture of dyes, antiseptics, fungicides, niacin, pharmaceuticals, and 8-hydroxyquinoline sulfate. Quinoline is a base that combines with strong acids to form salts, e.g., quinoline hydrochloride.
- Sulfanilamide ( $C_6H_8N_2O_2S$ ) = White, odorless crystalline sulfonamide, used in the treatment of various bacterial infections. Synonyms: Albexan; albosol; ambeside; *p*-aminobenzene sulfamide; sulfanilamide purified; bacteramid; 4-aminobenzenesulfonamide.
- Tributyltin (TBT) ( $(C_4H_9)_3Sn^+$ ) is an organotin compound used primarily as a biocide in anti-fouling paints. It is extremely toxic to aquatic life and is an endocrine-disrupting chemical that causes severe reproductive effects in aquatic organisms. Organotins are compounds consisting of one to four organic components attached to a tin atom via carbon–tin covalent bonds. When there are fewer than four carbon–tin bonds, the organotin cation can combine with an anion such as acetate, carbonate, chloride, fluoride, hydroxide, oxide, or sulfide.
- Triphenyltin (TPTH) ( $C_{18}H_{16}OSn$ ); Synonyms: triphenyltin hydroxide.

### Introduction

Human activity and its associated impact cause important changes over natural water composition leading frequently to pollution of the natural water resources. The pollution risk involved makes necessary the establishment of different quality levels according to the various uses of water (human consumption, industrial and agricultural use, etc.). Different effluents can affect water quality. Domestic effluents usually have fairly uniform characteristics despite being of heterogeneous nature, whereas industrial effluents display a broader diversity due to both between-industry and within-industry variations.

Sewage can be defined as water that has been changed in its characteristics by domestic, industrial, or agriculture effluents.

Urban sewage originates mainly from domestic sources and also from rain, and to a lesser extent from public cleaning-up, watering, wastewaters from industry emptied into municipal collectors, etc. Whereas literature information on the characteristics of urban sewage is abundant, industrial sewage should be addressed in a particular way.

Discharging of sewage to rivers and coasts has been a common practice in the past, hence causing strong changes in biotic conditions. Natural degradation processes occurring in any environmental compartment are slow so that suitable treatment is required for removal, or at least, decreasing the initial loadings up to an acceptable level. Treatment addressed to purification of sewage effluents are carried out in sewage treatment plants following different guidelines (e.g., EPA guidelines in USA, EU directives in Europe).

Analytical measurement of sewage is required to establish the appropriate treatments as well as to provide a measure of treated effluent quality and for optimization of the treatment processes. Apart from sewage itself, solid residues originated in treatment plants require analytical characterization regardless their final purpose (i.e., use as a resource or discharged).

The elimination and fate of sewage sludge originating in sewage treatment plants is assuming great importance. There are two major kinds of sludge generated in a waste treatment plant. The first

of these is organic sludge from activated sludge, trickling filter, or rotating biological reactors. The second is inorganic sludge from the addition of chemicals, like iron chloride or aluminum sulfate as in phosphorus removal. Most commonly, sewage sludge is subjected to anaerobic digestion in a digester designed to allow bacterial action to occur in the absence of air. Following digestion, sludge is generally conditioned and thickened to concentrate and stabilize it and make it more dewaterable.

Some of the alternatives for the ultimate disposal of sludge include land spreading or incineration. Each of these choices has disadvantages, such as the presence of toxic substances in sludge spread on land, or the high fuel cost of incineration.

### Chemical Pollutants in Sewage

Typical domestic sewage contains oxygen-demanding materials, sediments, grease, oil, scum, pathogenic bacteria, viruses, salts, algal nutrients, pesticides, heavy metals, etc. Several characteristics are used to describe sewage. These include turbidity, suspended solids, total dissolved solids, acidity, and dissolved oxygen.

Generally, early objectives concerning sewage treatment were related to elimination of suspended solids, biodegradable organic matter, pathogen organisms, and nutrients (P, N). Nowadays, sewage treatment does not only focus on environmental issues, but also on removal of toxic compounds at trace level, which may cause health problems in the long term. Main pollutants to be removed in the treatment are shown in **Table 1**, including both organic and inorganic substances. A primary issue concerning pollution by organics is dissolved oxygen decrease occurring as a result of biodegradation.

A brief description of typical parameters to be taken into account in the analytical characterization of sewage is given below.

#### Physicochemical Parameters

**Redox potential** This measurement is important since redox conditions of water affect the environmental behavior of many elements. The potential can be measured electrometrically by using an inert metal electrode.

**pH** This parameter is closely related to the redox properties of the system. In addition it dictates many water processing steps (e.g., acid–base neutralization, softening, precipitation, coagulation, disinfection,

**Table 1** Relevant pollutants in sewage treatment

<i>Pollutants/parameters</i>	<i>Concentration (mg l<sup>-1</sup>)</i>	<i>Remarks</i>
<i>Solid material</i>		
Total solids (TS)	350–1200	Organic matter can give rise to dump and anerobial conditions when discharged
Total dissolved solids (TDS)	250–850	
Suspended solids (SS)	100–350	
Sedimentable substances	5–20	
<i>Biodegradable organic matter</i>		
Biochemical oxygen demand (BOD <sub>5</sub> )	110–400	Biodegradable organic matter can cause an oxygen decrease in water
Total organic carbon (TOC)	80–290	
Chemical oxygen demand (COD)	250–1000	
<i>Nutrients</i>		
Total nitrogen Kjeldahl (NTK)	20–85	Nutrients are essential for life. Excess nutrients can give rise to eutrophication
Ammonium	12–50	
Nitrates	0.1–0.4	
Nitrites	0–0.1	
Total phosphorus	4–15	
Inorganic phosphorus	3–10	
<i>Pathogens (no. per 100 ml)</i>		
Total coli, salmonella, etc.	10 <sup>6</sup> –10 <sup>9</sup>	Disease transmission
<i>Refractory organic matter</i>		
Surfactants	2–6	Organic matter resistant to conventional treatments
Phenols	0.5–1	
<i>Inorganic dissolved solids</i>		
Chlorides	30–100	Salinity of water is increased. This can cause some problems during treatments (e.g., corrosion)
Sulfate	20–50	
Alkalinity (as Na <sub>2</sub> CO <sub>3</sub> )	50–200	
S <sup>2-</sup> , F <sup>-</sup> , Ca, Na, K, Fe, Al, etc.		
<i>Priority pollutants</i>		
Heavy 'metals' (As, Cd, Hg, Cr, Pb, etc.), CN <sup>-</sup> , chlorinated hydrocarbons (CHCs), polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), pesticides, dioxins/furans, etc.	μg l <sup>-1</sup>	Organic and inorganic compounds with carcinogenic, mutagenic, or toxic character

and corrosion control). pH measurements are made potentiometrically.

**Conductivity** This parameter helps to establish water quality and its temporal changes. Also, it allows dissolved solids to be quantified. This parameter is measured by conductimetry and is related to the total ionic concentration.

**Temperature** It influences the solubility of salts and gases. This parameter also affects electric conductivity through dissociation of salts, potential, and pH.

**Decantable water and suspended matter** Decantable water is quantified by allowing a given volume of water to stand for 2 h and then measuring the volume of the decanted water. Suspended matter can be determined by sedimentation, filtration, or centrifugation.

### General Chemical Parameters

**Salinity** This parameter is defined as the total amount of solutes in water after conversion of carbonates into oxides (and bromides and iodides into chlorides) and oxidation of all organic matter. It is often determined from conductivity measurements.

**Hardness** It is the combined concentration of all metal cations present except those of alkali metals and the proton. It includes to a large extent the contributions of Ca<sup>2+</sup> and Mg<sup>2+</sup>. The most usual determination, total hardness, involves titration with ethylenediaminetetraacetic acid (EDTA) in ammonia-ammonium buffer at pH 10 with Net as indicator.

**Acidity and alkalinity** Water acidity is defined as the capacity to react with a strong base up to a given

pH value. Total acidity is determined by titration with NaOH up to the color change in phenolphthalein (pH 8–9) while mineral acidity is obtained by titration in the presence of Methyl Orange as indicator (pH 5). Water alkalinity is defined as the capacity to react with a strong acid up to a preset pH. A titration with a mineral acid using phenolphthalein (free alkali and alkali carbonate contents) or Methyl Orange (total alkalinity) as indicators is performed.

### Heavy Metals and Arsenic

These are among the most harmful pollutants in sewage. Essential elements (e.g., Fe) as well as toxic metals such as Cd, Hg, and Pb are included. Main sources of heavy metals are industrial wastes, mining, fuels, coal, metal plating, etc. Metal determinations in sewage are preferably carried out by atomic spectrometry (flame and electrothermal atomization), atomic emission spectrometry, inductively coupled plasma-mass spectrometry, stripping voltammetry, spectrophotometry, and kinetic methods. Hg is advantageously determined by the cold vapor technique and As by the hydride technique.

### Anionic Species and Gases

These can be classified as nutrients (basically nitrogen- and phosphorus-containing species such as nitrate, nitrite, orthophosphate, polyphosphate, organic phosphate), toxic species (cyanide), and others (sulfide, sulfate, sulfite).

**Cyanide** It is a very toxic species. Cyanide is widely used in industry, especially for metal cleaning and electroplating. It is determined following distillation. Cyanide ion is released on acidification and collected in an NaOH solution where it can be quantified by titration with  $\text{AgNO}_3$ .

**Nitrogen-containing species** The nitrate content in waters is usually low but can rise to appreciable levels in farming wastewater as a result of soil fertilization. Nitrite originates from the microbiological reduction of nitrate or the oxidation of ammonia. Nitrite is usually determined spectrophotometrically using the Griess reaction. Nitrate is determined by the same method after prereduction to nitrite.

Ammonia is the initial product of the decay of nitrogenous organic wastes, its presence being an indication of such wastes. It originates from the deamination of nitrogen-containing organics and the hydrolysis of urea. Ammonia is usually determined by photometric, volumetric, or potentiometric methods.

**Phosphorus-containing species** This is one of the major nutrients in waters. It usually comes from fertilization, detergents, and animal and plant decay. Excess phosphorus and other nutrients in sewage are responsible for eutrophication. The most recommended method for its determination is spectrophotometry after formation of the molybdophosphate heteropolyacid and reduction to molybdenum blue.

**Sulfur-containing species** The most toxic sulfur species in waters are  $\text{S}^{2-}$  and  $\text{SO}_3^{2-}$ . Sulfide ion in sewage comes from sulfur-containing proteins and other organic compounds in feces and from industrial effluents. Sulfide ion can be determined spectrophotometrically by formation of Methylene Blue. Sulfite ion is present in some industrial sewages (textile, cellulose) and can be determined iodometrically. Sulfates in sewage come from some industrial processes and cause an increase in the salt load of the receiving stream. Sulfate ion is determined gravimetrically as  $\text{BaSO}_4$ .

**Dissolved oxygen** It is directly related to the concentration of organic matter, which uses oxygen for its bacterial degradation. Analytical determination of dissolved oxygen can be performed by the Winkler method or using membrane electrodes (polarographic and galvanic).

### Organic Parameters

**Biochemical oxygen demand (BOD)** The degree of oxygen consumption by microbially mediated oxidation of pollutants is called BOD. This parameter is commonly measured by determining the quantity of oxygen required by suitable aquatic microorganisms during a 5-day period ( $\text{BOD}_5$ ).

**Chemical oxygen demand (COD)** It consists of the amount of oxygen required for the organic matter to be oxidized by a chemical oxidant (e.g., potassium dichromate). For many wastewaters, a correlation between COD and  $\text{BOD}_5$  can be established which is advantageous due to the shorter time required to complete COD determinations.

**Total organic carbon** It refers to the amount of organically bound carbon present in sewage. Its measurement is based on the oxidation of organic carbon to  $\text{CO}_2$ , which can be subsequently determined by several methods (e.g., volumetric, gravimetric, conductimetric, coulometric).

**Detergents, soaps, detergent builders** Detergents are the primary source of domestic wastes in addition

to fecal matter and meal leftovers. Traditional detergents containing phosphates are banned in many countries to avoid eutrophication. Nowadays, only biodegradable detergents are allowed.

**Biorefractory organics** These are a group of great importance, including mainly aromatic or chlorinated hydrocarbons. These compounds are not completely removed by the biological treatment, other treatments such as stripping, solvent extraction, ozonation, and carbon adsorption being necessary.

**Pesticides** These are substances with biological action that can be classified into insecticides, fungicides, herbicides, etc. Insecticides in sewage come mainly from agriculture applications. Organophosphorus and carbamate pesticides have replaced organochlorine pesticides, which have been banned due to their high toxicity, persistence, and bioaccumulation in the environment. Gas chromatographic methods are employed for volatile pesticides. Liquid chromatography is recommended for pesticides with low thermal stability.

**Phenols** The term 'phenols' is used to designate a series of hydroxyl derivatives of benzene, with phenol as the parent compound. These compounds come from paper mills and cellulose factories as well as from degradation of pesticides such as carbaryl. Disinfecting treatments of chlorine-containing waters produce chlorophenols, which cause a persistent taste. Analytical control of these compounds is commonly performed by chromatographic or photometric methods.

**Other organic compounds** Other dangerous substances include hydrocarbons (fats and oils), polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and dioxins. Chromatographic methods (gas or liquid chromatography) are extensively used for separation and quantification of these groups.

## Treatment for Sewage Purification

There is a wide variety of treatment suitable for sewage purification that may be classified according to its nature, i.e., physical, chemical, thermal, or biological. In physical treatment, solid removal processes are involved. Some modification of the chemical structure of pollutants is developed in chemical treatment so that total degradation or separation is feasible. Thermal treatments use high temperatures for decomposition of pollutants, but high costs are normally involved, so they are mainly used for refractory substances, which are difficult to remove by other treatments. In biological treatment, microorganisms are applied to the sewage for degradation of organics and formation of biological flocs that can be easily separated. Typical sewage treatments are shown in Table 2. The suitability of treatments to the different pollutants is shown in Table 3.

According to the size of solids originally present in sewage, current processes for the treatment of wastewater may be divided into the following main categories of pretreatment, primary treatment, secondary treatment, and tertiary treatment.

During the pretreatment, solid particles are removed, physical procedures being mostly involved. Primary treatment of wastewater consists of the removal of insoluble matter such as grit, grease, and scum from water. Secondary wastewater treatment is designed to remove BOD, but also involves removal of nitrogen by denitrification, usually by taking advantage of the same kind of biological processes that would otherwise consume oxygen in water receiving the wastewater. Tertiary waste treatment (sometimes called advanced waste treatment) is a term used to describe a variety of processes performed on the effluent from secondary waste treatment. The contaminants removed by tertiary waste treatment fall into the general categories: (1) suspended solids, (2) dissolved organic compounds, and (3) dissolved inorganic materials, including the important class of algal nutrients. In addition to these chemical contaminants, secondary sewage

effluent often contains a number of disease-causing microorganisms, requiring disinfection in cases where humans may later come into contact with the water.

## Analytical Control in Sewage Treatment Plants

Before considering parameters to monitor in a sewage treatment plant, it is useful to briefly describe the different pathways involved during purification.

Figure 1 shows a block diagram of a typical sewage treatment plant. The sewage pathway includes different treatments addressed to water purification (Table 2); the sludge pathway includes a diversity of treatments for the solid residues (i.e., sewage sludge) generated during sewage purification. These treatments include sludge conditioning, concentration, dehydration, and digestion and depend on the sludge properties and final disposal, leading to volume reduction and lower fermentation power. The gas pathway is related to the anaerobic digestion process, which generates gases such as methane and carbon dioxide; finally, the residue pathway includes

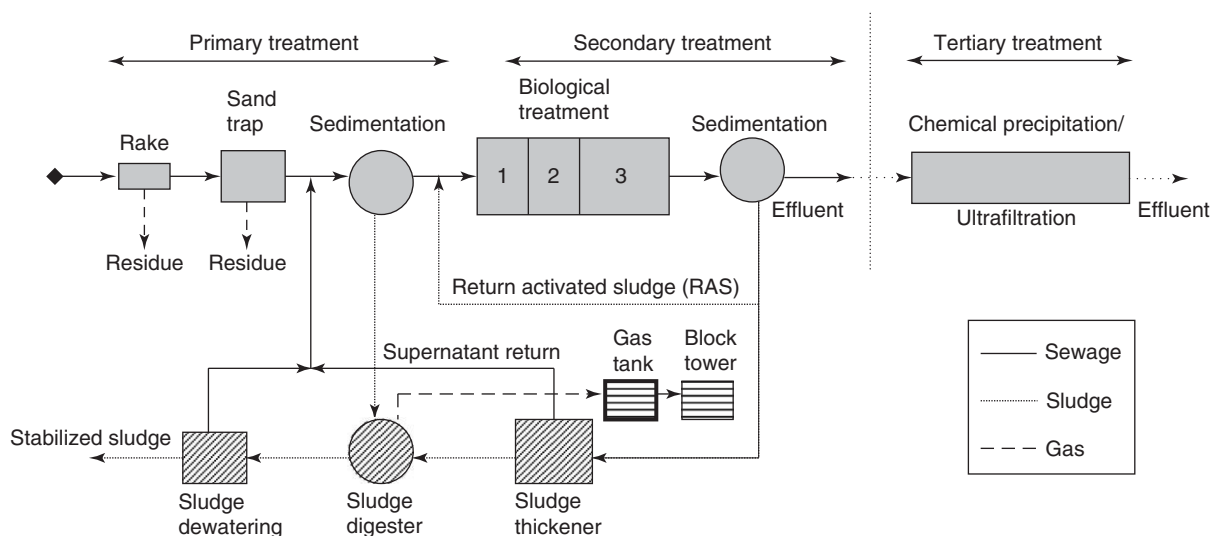

those pollutants separated during the pretreatment process.

### Analytical Control in the Sewage Pathway

Analytical determinations of relevant parameters in sewage are performed following reference methods, widely applied to both potable waters and wastewater (Table 4).

It is important to emphasize that representative samples must be collected before any analytical determination is performed. Factors such as sampling point, sample volume, sampling times, number of samples should be considered.

Typical analytical determinations are carried out at the sewage input of the treatment plant, outlet of the mechanical treatment, biological treatment stage, and sewage outlet into the waters. Temperature, pH, conductivity, sedimentable substances, suspended solids, COD, and BOD<sub>5</sub> are the parameters determined in all the points mentioned above. Alkalinity, NTK (total nitrogen Kjeldhal), ammonium, nitrite, orthophosphate, total phosphorus, sulfate, phenols, tenside, and lipophilic substances are primary parameters at the input, biological treatment, and outlet. Generally, analysis at both the input and outlet is

**Figure 1** Block diagram of a sewage biological treatment plant: (1) anaerobic conditions, biological phosphorus elimination, (2) denitrifying stage, and (3) aerobic conditions, oxidation of organic compounds.

important for the determination of substances that either affects treatment (e.g., aluminum and iron in case of chemical elimination of phosphorus) or are priority pollutants. In the latter, it is important to establish the purification degree taking into account the industrial activity in the area (e.g., heavy metals, cyanides, PCBs).

For control purposes as well as for modeling treatment plants, the most important parameter may be the characterization of organic matter. Dissolved oxygen levels determine water quality, but also indicate the possibility of bad odor.  $BOD_5$  is always monitored in sewages, its importance lying in three different features concerning treatment plants: (1) estimation of the oxygen required for biological stabilization of the organic matter present, (2) estimation of the size of facilities for the biological treatment of wastewater, and (3) assessing the treatment efficiencies.

Analytical control of a large number of routine parameters has driven developments in two areas: (1) automation and (2) sample handling. Thus, multiparameter probes allow determination of different parameters (e.g., total solids, COD, TOC, and nitrate) in different points of the treatment plant thereby avoiding sample handling and sampling.

Monitoring water pollution in a continuous manner provides more thorough information. Online analyzers are especially valuable in analytical control of many parameters in sewage treatment plants. Thus, parameters such as alkalinity, hardness, pH, COD,  $NH_3$ ,  $Ca^{2+}$ ,  $Cl^-$ ,  $F^-$ ,  $NO_3^-$ ,  $PO_4^{3-}$ ,  $SiO_3^{2-}$ ,  $SO_4^{2-}$ , and various metals can be determined using single-pollutant photometric analyzers. There are also automated methods for dissolved oxygen, conductivity, redox potential, and turbidity. Multipollutant

analyzers are of greater interest than those for single pollutants (e.g., Inductively coupled plasma-atomic emission spectroscopy (ICP-AES) and stripping voltammetric detectors for determination of multiple metals in waters).

With regard to the secondary treatment, monitoring of temperature, pH, dissolved oxygen, organic matter, and nutrients is needed to maintain the micro-organism activity under control. Thus, the  $BOD_5/COD$  ratio is employed as an estimation of the degradation capacity, being used for checking micro-organism activity.

On the other hand, it is necessary to monitor certain substances that can inhibit enzyme activity (e.g., insoluble salts, metal ions, etc.). These inhibiting substances can destroy or reduce the biodegradation capabilities of the activated sludge bacteria in the treatment plant, giving rise to an increase in treatment time and consequently to increase in cost. Toxicity can be estimated by a toxicity-direct analysis based on classical bioassays, measuring the inhibition percentage of respiration rate in activated sludge. This test is too laborious, and the use of biological test systems based on living cells or sub-organisms, e.g., inhibition of the bioluminescence of luminescent bacteria, is recommended. Also, the toxicity test is employed to assess environmental risk due to specific pollutant groups.

### Analytical Control of Sewage Sludge

A large variability exists in the sewage sludge composition depending on the origin and treatment of sewage. Sewage sludge of municipal origin contains high amounts of organic matter (i.e., >60%), apart

from significant inorganic fraction formed by  $\text{SiO}_2$ ,  $\text{Fe}_2\text{O}_3$ ,  $\text{CaO}$ ,  $\text{P}_2\text{O}_5$ ,  $\text{Al}_2\text{O}_3$ , and  $\text{K}_2\text{O}$ . Sewage sludge is rich in nutrients, containing  $\sim 5\%$  N,  $3\%$  P, and

$0.5\%$  K on a dry-weight basis, and can be used to fertilize and condition soil. Among the factors limiting this application of sewage sludge are excess

**Table 4** Standard methods for analysis of sewage

Contaminants/parameters	Method
<i>Physical and aggregate properties</i>	
Color	Visual comparison, spectrophotometric tristimulus filter
Turbidity	Nephelometric
Acidity/alkalinity	Titration
Hardness	EDTA titration
pH	Electrometric method
Salinity	Electrical conductivity
Flotables	Trichlorotrifluoroethane-soluble floatable oil and grease
Solids	Total solids dried at $103\text{--}105^\circ\text{C}$ , total dissolved solids dried at $180^\circ\text{C}$ , total suspended solids dried at $103\text{--}105^\circ\text{C}$ , fixed and volatile solids ignited at $550^\circ\text{C}$ , settleable solids (volumetric or gravimetric test); total, fixed, and volatile in solid and semisolid samples
<i>Tests on sludges (uniquely applicable to sludges or slurries)</i>	
Oxygen-consumption rate	Oxygen probe
Settled sludge volume	Settling columns, sludge volume index (SVI)
Zone settling rate	Settling vessel
Specific gravity (SG)	Weight of sample and weight of equal volume of water
Capillary suction time	The CST meter characterizes the sludge dewatering processes
Anaerobic sludge	Volumetric method, gas chromatographic, dissolved gas supersaturation
Digester gas analysis	(direct-sensing membrane diffusion method)
<i>Metals</i>	
	Acid digestion or extraction, atomic absorption spectrometry (flame, cold vapor, hydride generation, and electrothermal), emission spectroscopy (plasma and flame), spectrophotometry, anodic stripping voltametry
<i>Inorganic nonmetallic constituents</i>	
Anions	Ion chromatography
Boron	Spectrophotometry
Cyanide	After distillation, spectrophotometry, ion-selective electrode
Chlorine	Titrimetric, potentiometric, amperometric, colorimetric
Fluoride	Distillation, ion-selective electrode, colorimetric
Iodine	Colorimetric, amperometric titration
Nitrogen	Ammonia (distillation, titrimetric, ammonia-selective electrode, phenate method); nitrite (ion chromatography, colorimetric); nitrate (ultraviolet spectrophotometric screening, nitrate electrode, reduction); organic (Kjeldahl, persulfate method)
Dissolved oxygen	Iodimetric and modifications, membrane electrode
Phosphorus	Acid digestion, colorimetric methods
Silicon	Gravimetric, atomic absorption spectrometry, colorimetric
Sulfide	Colorimetry, iodometric, ion-selective electrode
Sulfate	Gravimetric, turbidimetric, colorimetric
<i>Aggregate organic constituents</i>	
Biochemical oxygen demand (BOD)	Five-Day BOD test, ultimate BOD test, respirometric method
Chemical oxygen demand (COD)	Reflux method, titrimetric, colorimetric
Total organic carbon (TOC)	Combustion-infrared, persulfate-ultraviolet oxidation, wet oxidation
Dissolved organic halogen (DOX)	Adsorption-pyrolysis-titrimetric method
Oil and grease	Partition-gravimetric, partition-infrared, extraction
Phenols	Extraction (total phenols), distillation (volatiles), colorimetry
Surfactants	Separation by sublation, methylene blue active substances (MBAS), anionics and cobalt thiocyanate active substances (CTAS), nonionic surfactants
Organic and volatile acids	Chromatographic, distillation
<i>Individual organic compounds</i>	
Volatile organic compounds, polychlorinated biphenyls (PCBs), pesticides, etc.	Purge and trap, extraction, gas chromatography, high-performance liquid chromatography, mass spectrometry

nitrogen pollution of runoff water and groundwater, survival of pathogens, and the presence of heavy metals in the sludge. The presence of heavy metals such as Pb, Cd, Cr, Cu, Hg, Ni, and Zn can preclude its application as a source of nutrients for crop land, mainly for prolonged use on soil.

Apart from heavy metals, other undesirable components typically found in sewage sludge are some organics (e.g., PCBs, pesticides, phenols, etc.) and pathogenic microorganisms (e.g., salmonella, fecal coliforms, etc.). While microorganisms can be destroyed by several treatments (aerobic and anaerobic digestion, composting), accumulation of heavy metals is of greatest concern for the use of sewage sludge in agriculture.

It has been widely recognized that prolonged application of sewage sludge on land can cause soil to be enriched with heavy metals, which, in turn, can reach the food chain. Different countries have enacted regulations to limit the heavy metal (Hg, Cd, Pb, Cr, Cu, Ni, and Zn) content in sewage sludge used for agriculture purpose.

Analysis of sewage sludge for metal determination must be performed at least every 6 months, with atomic spectrometry techniques mostly recommended (e.g., flame-atomic absorption spectrometry; electrothermal atomic absorption spectrometry; inductively coupled plasma-atomic emission spectrometry). Despite the need for only total metal amount, mobility and bioavailability studies must include some metal partitioning by sequential extraction. For this purpose, a number of extractable fractions with environmental significance are obtained using sequential extraction schemes such as that of BCR (The Community Bureau of Reference, now Standards, Measurements and Testing Programme) (fractions: acid soluble, reducible, and oxidizable) and Tessier (fractions: exchangeable, carbonate-bound, Fe–Mn oxides-bound and organic matter-bound).

## Organic Compounds

M R Preston, University of Liverpool, Liverpool, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

The low concentrations at which most organic compounds appear in water (typically  $1:10^{-10}$ – $10^{-12}$ )

pose a number of significant challenges to the analytical scientist. These challenges relate to both sensitivity and selectivity of the analytical method and have generally required isolation/preconcentration steps to address the former and fractionation procedures to achieve the latter. Clearly, the ultimate ambition for analytical chemists is to achieve (near)

real-time determination of all the compounds of interest in a particular situation with a minimum number of steps in the procedure. Multicompound, *in situ* probes are still some way off in most cases. Nevertheless, it is noticeable that in the past few years there has been significant progress in this direction through the exploitation of advances in sample extraction and detection (primarily hyphenated mass spectrometric techniques).

It must be remembered that the analysis itself is rarely the primary goal. The need to measure the concentration of a compound or group of compounds is usually determined by its real or potential impact on the system in which it occurs. Many of the developments in recent analytical procedures relating to the analysis of organic compounds in water therefore derive from the presence of the compounds on lists of Priority Pollutants (e.g., US Environment Protection Agency list of 307 compounds or the UK Department of the Environment, Fisheries and Rural Affairs list of 'Chemicals of Concern'), quality standards for drinking waters (e.g., disinfection by-products), or because they have suspected deleterious effects (e.g., endocrine disrupting chemicals, EDCs). Modern developments have, in many cases, led toward online or automated systems that not only allow a greater sample throughput but also reduce sample handling and thus the risks of sample contamination. However, the difficulties of obtaining reliable quantitative data of trace organic compounds in water are not to be underestimated and great attention must always be paid to the provision of appropriate quality assurance and quality control procedures.

It is worth noting that the analysis of organic contaminants in freshwaters presents different analytical challenges to those encountered in seawater. River and lake water concentrations of both natural and contaminant organic compounds are generally higher than seawater (as also may be the suspended particle loadings) but the background concentrations of humic and fulvic acids in the former may cause particular difficulties by, for example, overloading extraction devices. The presence of colloidal species in the freshwater environment may also be of greater import in determining the speciation of organic molecules than in marine systems. Potable water systems are very largely free of these problems but may contain higher proportions of volatile halomethane compounds created during water treatment processes. The high mineral content of groundwater may also provide sampling and analytical challenges where concentrations of inorganic species are high (and often variable) whilst those of organic compounds are very low. As a

general rule, it is probably true to say that analytical methods developed for seawater analysis will often be satisfactory in the freshwater environment but the converse is not true.

## Dissolved versus Particulate Organic Matter

The issue of separating organic compounds in water into solid and particulate phases is nontrivial. Organic species may occupy a size distribution that encompasses a spectrum of physical states from the truly dissolved to the unambiguously particulate. Between these states lie the complications. Traditionally, filtration through a preweighed membrane (typically 0.45  $\mu\text{m}$ ) or glass fiber (0.7–1.0  $\mu\text{m}$ ) filter has been the method of choice. However, this is a purely operational distinction and the use of other filter media such as polytetrafluoroethylene, silver, or aluminum filters can have a significant impact on the determined solid/liquid speciation (and expense). A number of experiments in recent years have identified a so-called third phase. This is essentially colloidal material that passes through a conventional filter and yet can have a significant impact on the apparent partitioning coefficients of organic species in natural systems. To add complications to an apparently simple procedure, the act of filtration itself may alter partitioning and worse, the degree of this effect may alter as the filter clogs and its filtration characteristics change. A further complication is that some filters may be supplied loaded with wetting/stabilizing agents that are organic in nature and which must be removed if contamination of the filtrate is to be avoided. Glass fiber filters are normally pre-ashed (by heating to 400–420°C for several hours), but this can lead to the formation/exposure of active sites within the filter capable of adsorbing sample components. Other filter types may also exhibit sorptive properties though these are rarely taken into account.

The filtration process itself is a mechanically aggressive one, particularly for delicate unicellular organisms such as the phytoplankton that are abundant in natural waters. If filtration is performed without due regard for this problem, cells may rupture spilling their contents into the filtrate. To avoid this problem vacuum filtration is probably only satisfactory under weak (<0.25 bar) vacuum and pressure filtration is generally more satisfactory.

Therefore, to obtain truly valid comparisons within the same sample set, let alone between different sets or different scientists and laboratories, is a very challenging task. One resolution of the problem is to avoid the filtration step entirely and analyze the whole sample. This approach has value

in some circumstance where, for example, variations in sample composition are small but it is not without its limitations and is potentially seriously flawed where the detailed effects of the presence of a specific compound are to be determined or modeled.

### Analysis of Total Dissolved Carbon

The dissolved organic carbon reservoir in natural waters represents a very significant component of the carbon cycle but reliable quantitative determination of this parameter has proved to be difficult particularly in seawater. Commercially available systems are better suited to freshwaters though obtaining accurate results is still not a trivial exercise and great care must be taken to ensure that blanks are satisfactorily and consistently low and that precision remains consistent.

### Preconcentration/Extraction Strategies

With the exception of highly sensitive methods such as the determination of amino acids in water using precolumn derivatization followed by liquid chromatography (LC)-fluorescence, virtually all other determinations require a preliminary preconcentration stage. Traditional procedures such as lyophilization and vacuum distillation are now rarely used because they are time consuming and unsuitable for compounds with significant volatility. Whilst reverse osmosis and ultrafiltration, or, its more recent variant tangential flow ultrafiltration, have found applications, they are again slow and susceptible to considerable unpredictability in their performance. This section therefore focuses on those techniques that have seen increased usage in recent years.

### Extraction of Particulate Organic Compounds

Traditional Soxhlet extractions are still widely used though increasingly being supplanted by faster technologies. Supercritical fluid extractions have not always lived up to their initial promise and the modern trends are toward microwave or pressurized liquid extractions (PLEs) using conventional solvents. Water itself can be used as the extracting solvent in subcritical water extraction (SWE). Analytical recoveries using PLE and SWE are often superior to those obtained by traditional methods as well as being much more rapid.

These techniques are not necessarily used alone. Some recent reports combine PLE with solid-phase extraction (SPE) technologies that include the use of

restricted access materials and liquid chromatography-mass spectrometry (LC-MS) to measure alkyl-phenolic compounds and steroid sex hormones in sediments.

### Extraction of Dissolved Organic Compounds

Classical methods such as liquid-liquid extraction (LLE) are comparatively rarely employed now because of their twin disadvantages of being slow and unwieldy where large sample volumes are to be extracted. The past decade has seen major advances in sorptive extraction techniques such as SPE or solid-phase microextraction (SPME), semipermeable membrane devices (SPMDs), and even stir bar sorptive extraction (SBSE). Such devices rely on the equilibrium (sometimes nonequilibrium) partitioning of analytes between aqueous and solid phases.

SPE is presently the most important technology for the isolation of organic compounds from water and SPE cartridges and disks have found a large number of applications. Numerous SPE systems that may be general purpose (e.g., alkyl silica or polymer) or class specific (molecularly imprinted polymers or immuno-affinity solid phases) are on the market. When these are coupled with the increasing availability of LC-mass spectrometry (MS) systems, sometimes in in-line format (i.e., SPE-LC-MS), the number and range of published applications is increasing rapidly. The recent development of molecularly imprinted solid-phase extraction (MISPE) is leading to an increasing range of applications including the extraction of triazine herbicides, sulfonyl urea, and chlorinated phenoxyacid herbicides from surface water samples and 4-nitrophenol from river water using online MISPE-reversed phase LC.

SPME technology is normally based on hollow fibers internally coated with a very small (typically 500 nl) quantity of suitable adsorbent. The great advantages of this technology are its relatively low cost, compatibility with both aqueous and gaseous samples, and its ease of integration into gas chromatographic (GC) systems. Numerous types of SPME coatings are now on the market giving a rapidly increasing range of applications. Some organometallic species have also been extracted using SPME. One significant advantage of SPME extraction is that the quantity of analyte removed from the system is normally a negligible proportion of the whole. This so-called 'negligible depletion solid-phase microextraction' does not alter the fundamental equilibrium within the system under study, so allowing estimates of true bioavailability to be made; a result that is very difficult to achieve using conventional systems.

Further recent developments in fiber SPME have extended applications to compounds with low volatilities and/or low thermal stability. Thus, fiber- (or tube-) based SPME–LC has a considerable future potential, particularly as it has been recognized that GC capillary columns (available with a very wide range of internal coatings) can be used for this purpose. Samples are pumped through the tube using a micropump and then eluted onto the LC column using appropriate solvents. Applications of in-tube SPME (in combination with LC) include phthalates, chlorinate phenoxy acid herbicides, tributyl tin compounds, polyaromatic hydrocarbons (PAHs), and polar aromatic compounds in water.

SBSE is a variation of SPME where a polydimethylsiloxane-coated stirrer bar is used in place of a sorbent-coated fiber. The extraction is conducted by simply placing the bar in the sample solution and using a magnetic stirrer to stir it. Because the bar is relatively large in size the quantity of sorbent on its surface is also large, giving it a high sorption capacity yielding improved analyte recovery and sensitivity. To retrieve the sorbed materials from the bar it is placed in a thermal desorption unit (for GC analysis) or simply washed in solvent (for LC analysis). See Table 1 for a summary of applications of SPE variants.

### Semipermeable Membrane Devices

The underlying concept behind SPMDs is that an adsorptive material is enclosed within a semipermeable membrane thereby allowing compounds of interest to passively diffuse into the bulk adsorbent over time. To an extent this mimics the natural situation where chemicals passively diffuse into the fatty

tissues of exposed organisms. Compounds suitable for SPMD extraction are hydrophobic ( $\log K_{ow} > 2$ ) and nonionic. Whilst a variety of sorbents have been tried, the commonest is triolein. Applications include extraction of PAH, polychlorinated biphenyl (PCB), polybrominated diphenyl ether (PBDE – flame retardants), and methyl triclosan. SPMDs have had some applicability in the long-term integration of contaminant levels in natural waters and have also found a variety of applications in atmospheric sampling.

### Integrated Online Extraction and Detection Systems

The need for maximum sample throughput and minimal human interaction within analytical procedures has provided considerable impetus to the development of integrated systems. SPE–LC in-tube SPME followed by ultraviolet (UV) or MS detection and membrane introduction mass spectrometry (MIMS) have both been used to this end. Submersible MIMS systems capable of extended underwater deployment down to  $\sim 200$  m and with a mass range of up to 200 amu have recently come onto the market. Flow injection coupled with MIMS allows fast, near-real-time determination of, for example, phenols in water. Derivatization of the phenols with acetic anhydride can be used to enhance both the selectivity and sensitivity of this method. Other online derivatization procedures are under development with a view to increasing the scope for rapid determination of highly polar compounds that have previously proved difficult to analyze. Large volume injection techniques and developments in enzyme-linked immunosorbent assay (ELISA) technologies

**Table 1** Examples of compounds extractable using solid-phase extraction (SPE), solid-phase microextraction (SPME), and stir bar solid extraction (SBSE)

SPE	SPME	SBSE
Alkylphenols	Chlorinated paraffins	Organotin compounds
Alkylphenol ethoxylates	Chlorophenols, methyl <i>tert</i> -butyl ether	PAHs
Antimicrobials and antibiotics such as sulfonamides, tetracyclines, fluoroquinolone, and triclosan	Organochlorine and organophosphorus pesticides, biocides	PCBs
Bisphenol A		
Caffeine		
Dimethylbenzylammonium chloride		
Fragrance materials		
Perfluorinated surfactants		
Pesticides such as those in the triazine, phenylurea, phoxy acid, acetanilide, carbamate, organophosphorus, and pyridylium classes and their metabolites		
Pharmaceuticals such as ibuprofen, codeine and estrogens		
Phthalate esters		

are also helping to improve sensitivity and reduce analytical times. Other strategies, including a cryo-trapping step prior to MIMS, have been used for organohalogens in water with detection limits as low as parts per trillion.

One recent development that offers scope for direct injection of aqueous samples into an MS system is the high-field, asymmetric waveform ion mobility spectrometer (FAIMS). By interfacing the FAIMS technology to an ESI-MS instrument a significant reduction in detection limits has been achieved for molecules of <300 Da. Preconcentration is unnecessary and analytical times are significantly shortened. Recent applications of this technique include naphthenic and haloacetic acids in water and amphetamines, morphine and codeine in urine.

## Separation and Detection Methods

Numerous combinations of separation and detection methods have been reported in the literature and only some of the more important examples are discussed below. An overview of analytical strategies as applied to some important chemicals is given in Table 2.

### Gas Chromatography

GC remains the technique of choice for very many volatile or semivolatile analytes or samples that can be made volatile through derivatization. GC offers excellent sensitivity and selectivity and an increasingly wide range of detectors. Amongst the most significant developments in column technology in recent years has been the introduction of chiral columns (many based on  $\beta$ -cyclodextrin). The ability to separate enantiomers of, for example, semivolatile organic pollutants is a major new tool in environmental studies allowing significant insights into the mode of action of chemicals and differences in their degradation behavior. The use of enantiomer fractions to describe compounds such as chiral hexachlorobornane,  $\alpha$ -HCH, *trans*-chlordan, PCBs 95 and 136 has led to new insights into their behavior in biotic and abiotic environmental systems. Chiral phases in LC are as yet less well developed but it is to be anticipated that the availability and uses of such materials will become more important in the relatively near future.

Efforts to decrease analytical times have largely depended on improved response times in detectors. Fast GC, where complete separations are achieved in a few minutes, has a number of reported applications. Time-of-flight mass spectrometry (TOFMS) is often

the chosen detection system though some quadrupole systems also have sufficiently fast scan times to be of service. Rapid online MIMS systems have permitted parts per trillion analysis of several trihalomethanes in water with a sample throughput of  $\sim 20$  per hour. Fast GC in combination with TOFMS has been used for PCB analysis, as has GC with pulsed electron capture detection. Fast GC with inductively coupled plasma MS (ICP-MS) has been used for the determination of polybrominated diphenyl ethers in sewage sludge with low ppb detection limits achievable in an analysis time of  $\sim 10$  min.

Efforts to improve selectivity have introduced a trend from single GC columns to the use of two (or more) columns (two-dimensional GC). The advantages of such systems are in a huge ( $10 \times$ ) improvement in peak capacity over conventional GC allowing much more complex mixtures to be handled. Such systems are more complex than simply connecting two columns together and have only been successful because of improvements in hardware such as heated sweepers, cryofocussed modulators, and valve switching. Such systems have enormous potential to identify compounds of major environmental importance from an extremely complicated background matrix.

Improvements in column technology have led to the ready commercial availability of columns with chiral stationary phases that allow enantiomers to be separated. A similar result can be achieved through the use of chiral derivatization reagents. The ability to separate different enantiomers, which may have very different biological reactivities, has opened major avenues of research. In particular, it has allowed very significant reassessments of biological degradation rates of contaminant chemicals where one enantiomer may exhibit very different behavior to its mirror image.

GC detector technology has also developed in areas other than MS. Fourier-transform infrared spectrometry (FTIR) and atomic emission detection (AED) can both provide structural insights into eluted compounds. AED, in particular, allows analysts to move away from the carbon-based detection capabilities of the standard flame ionization detector to focus on other elements such as N, Cl, S, P, Br, and F allowing molecules with particular elemental constituents to be readily identified.

### Liquid Chromatography

Applications of LC and, in particular, LC-MS continue to grow. Much recent emphasis has also been placed on combined extraction/analytical systems with SPE and automated in-tube SPE-LC

**Table 2** Examples of analytical strategies applied to chemicals in water

<i>Compound</i>	<i>Sample preparation method</i>	<i>Analyte detection technique</i>
Acidic compounds	Goulden extractor versus SPE	GC-MS
Amines, aliphatic	Derivatization with 2,4-dinitrofluorobenzene or benzenesulfonyl chloride, solvent extraction with CH <sub>2</sub> Cl <sub>2</sub>	GC-MS
Atrazine, diuron, simazine, terbutylazine	SPE	LC-ESI-MS-MS
Atrazine	Direct injection	ESI-ion mobility spectrometry
Azo dyes, sulfonated	Direct injection	IC electrochemical detection
Bromocyclen	LLE, SPE	Chiral GC
Caffeine	SPE	GC-MS, GC-MS-MS
Carbendazim	Protein G immunoaffinity column	GC-MS-MS
2,4-Dinitrotoluene	None	Surface-enhanced Raman spectroscopy
2,4-Dinitrotoluene	Custom vapor sampler	Sensory polymers attached to fiber optics
Chemical warfare agents		Flow injection amperometric enzyme biosensor
Chloro-bispropyl ethers		Enantioselective GC-MS
Chloroethers	SPME	GC-MS
Chlorolignosulfonic acids	SPE	Curie point pyrolysis-GC-MS-MS
Clofibric acid	SPE, methylation with diazomethane	HRGC-MS-MS
Dinitroanilines	SPME	GC-ECD
1,3-Dioxanes, 1,3-dioxolanes	Closed loop stripping	GC-CI-MS or GC-EI-MS-MS
Diquat, paraquat, difenzoquat	SPE with graphitized carbon black	LC
EDTA	Lyophilization, esterification with ethanol	GC-NPD
Endocrine disrupting chemicals	SPE	GC-MS Microemulsion electrokinetic chromatography, capillary zone electrophoresis, micellar electokinetic chromatography (MEKC), cyclodextrin modified MEKC
Fluocofuron, sulcofuron	LLE, SPE	LC-ESI-MS-MS
Fluoroquinolone	SPE with mixed-phase cation exchange resin	LC/UV
Fragrance materials	SPE	Isotope dilution GC-MS
Geosmin (methylisoborneol)	Hexane microextraction	GC-MS
Haloacetic acids	Many methods, SPE, derivatization, headspace sampling	GC-MS, negative ion GC-MS
Ibuprofen	SPE Biobeads SM-2, methylation with diazomethane	Chiral GC-MS-MS-SIM or SRM
MTBE	Headspace SPME, purge and trap	GC-MS, MIMS
Organonitrogen pesticides	SPE with graphitized carbon black or LLE	GC-NPD, LC-APCI-MS
Organotin compounds	SBSE, derivatization	TD-GC-ICPMS
Organotin compounds	Ethylation, SPME	Multicapillary GC-AES
Organotin compounds	Ethylation, SPME	Isotope dilution GC-MS
Organotin compounds	Ethylation, LLE, PLE	Isotope dilution GC-MS
PCBs	Many methods, SPE polyurethane columns	GC-ECD, positive and negative ion GC-MS
Perfluorinated surfactants	SPE	LC-MS-MS, <sup>19</sup> F-NMR
Pharmaceuticals – hormones and other consumer products	SPE, continuous liquid extraction	LC-MS, GC-MS with and without derivatization
Pharmaceuticals (acid and neutral)	SPE (Oasis HLB sorbent) derivatization with diazomethane	GC-MS
Phthalate esters	LLE	GC-ECD, GC-SIM
Sulfonylurea, imadazolinone, sulfonamide	Spe with RP-102	LC-ESI-MS
Sulfonamide and tetracycline microbials	SPE	LC-MS
Triazines, acetamindes phenoxy acids	SPE with graphitized carbon black, derivatization with diazomethane	GC-MS
Triclosan	SPE, PLE	GC-MS, GC-MS-MS
Triclosan and methyl triclosan	SPE, dialysis, GPC derivatization	GC-MS
Triclosan and methyl triclosan	SPE, SFE, derivatization	GC-MS, GC-HRMS
Triclosan	SPE	GC-MS
Trifluoroacetate	SPE, extracted with MTBE, derivatized with pentafluorophenyldiazoethane	GC-MS (negative ionization)

systems being the subject of recent reviews. Important applications include analysis of estrogens and progestogens, pesticides, nonionic surfactants, phenols, and organotin and organophosphorus compounds in aqueous samples. Developments in micro-ELISA systems have in one application allowed the sample volumes for atrazine analysis to be reduced to 30  $\mu\text{l}$  permitting the determination of atrazine at levels of 0.022–2.90  $\mu\text{g l}^{-1}$ .

As in GC, the uses of LC for the separation of chiral species have significantly increased. Column materials now include chiral phases that may, for example, be based on monolithic silica columns with chemically bonded beta-cyclodextrin, teicoplanin, or cellulose tris(3,5-dimethylphenylcarbamate). Hydrophobic amino compounds have been separated by LC using a crown ether dynamically coated chiral stationary phase.

Chiral derivatization agents have found an increasing number of applications in drug analysis. Examples of such reagents include (–)-1-(9-fluorenyl)ethyl chloroformate or *o*-phthalaldehyde in combination with the chiral thiol *N*-acetyl-L-cysteine for amphetamine analysis, benzofurazan-bearing chiral derivatization reagents (drugs and other biologically important compounds), subsequent chiral derivatization with (–)-alpha-methoxy-alpha-(trifluoromethyl)phenylacetyl chloride (*R*-(+)- and *S*-(–)-metoprolol). Applications in environmental samples are more limited but include the separation of amino acid enantiomers using *o*-phthalaldehyde/*N*-isobutyryl-L-cysteine to yield fluorescent diastereomeric derivatives of chiral primary amino acids.

## Mass Spectrometry

The use of mass spectrometry in environmental analysis is now ubiquitous and has recently been reviewed by William L. Budde and (separately) by Susan Richardson. Whilst such a detailed review is clearly beyond the scope of this article, the reader is referred to other articles in this volume and the present section is restricted to highlighting a few relevant modern developments and they relate to analysis of organic compounds in water.

Developments in LC–MS have probably been greater than in GC–MS though that too has seen significant advances. LC–atmospheric pressure chemical ionization (APCI)–mass spectrometry has become particularly important and has found numerous applications in the determination of, for example, industrial mass chemicals such as dyes, aromatic sulfonates, surfactants, and complexing agents, and also trace compounds such as drugs, endocrine-disrupting compounds, toxins, phenols,

and haloacetic acids. LC–MS has, however, only had limited success in the characterization of natural organic matter though it is beginning to develop the potential for the study of organometallic compounds. LC–APCI–MS is, however, not without its difficulties. Both qualitative and quantitative analyses may be inhibited by the limited resolution of quadrupole and ion-trap MS and the limited fragmentation created through collision-induced dissociation. Matrix effects can create difficulties in quantitation, particularly when electrospray technologies are used. These problems are not impossible to solve and improvements in instrumentation such as tandem MS or TOFMS both offer considerable potential for improvements particularly when coupled with better chromatographic (or other) separations before introduction into the mass analyzer. Ion-mobility mass spectrometry has been developed into a field instrument initially for vapor-phase organic chemicals and chemical warfare agents. However, when coupled with electrospray ionization MS, nonvolatile and biological compounds can also be measured in aqueous field samples. This technique has been used for the determination of atrazine in natural water samples. There are some calibration problems with this technology but regardless of analyte properties and upper limit of  $10^{-5} \text{ mol l}^{-1}$  is commonly observed in most electrospray ionization systems.

New developments in analysis utilizing GC–MS have included GC–FTIR coupled with high-resolution EI and CI–MS to identify drinking water contaminants and GC–IR–MS to examine contaminated water, clay, and soil samples. GC–MS, LC–nuclear magnetic resonance (NMR), and LC–MS have been used to identify contaminants in industrial landfill leachate. Online systems have also been developed such as the measurement of organic contaminants in water samples. MIMS has allowed the development of commercial *in situ* devices that are now on the market (see above). Almost all combinations of preconcentration, separation, and mass detection have seen significant advances.

Isotope ratio MS (IRMS) is also receiving increasing attention as a tool for the identification of biomarkers and the tracking of chemicals from particular sources. Such systems generally employ a combustion stage between the GC and IRMS and are, therefore, sometimes designated GC–C–IRMS systems. Such a system has, for example, been used to track the isotopic enrichment of tetrachloroethene and trichloroethene (TCE) in groundwater. Down-gradient wells showed  $\delta^{13}\text{C}$  values as enriched as –18‰ as compared to delta C-13 values for TCE in the source zone of –25.0 to –26.0‰.

## Emerging Contaminants and Techniques

As a very rough rule of thumb it is probably true to say that for every order of magnitude increase in analytical sensitivity the number of detectable analytes also increases by a similar factor. Thus, chemists are, in principle, able to identify and quantify ever-smaller amounts of individual chemicals, be they natural products or contaminants. This raises considerable problems in a number of areas but particularly the time taken for analysis, data management, and interpretation. Analysts are, therefore, increasingly being forced to focus on a restricted number of target compounds within a complex matrix and these targets tend to be set by legal priorities as much as environmental ones. Priority pollutant lists enshrined in law are examples of such factors.

For example, much attention is being paid to organic compounds generated inadvertently as a result of water treatment processes. Disinfection by-products (DBPs) are a major area of analytical activity because of their potential toxicity to humans. Examples of such chemicals are given in Table 3. Analysis of DBPs includes the use of techniques such as LLE-GC-ECD (with or without prior derivatization), SPE-GC-MS, LC-APCI-MS, headspace-SPME-GC-ECD, SPE-ion pair-LC-ESI-MS, and purge-and-trap-GC-MS. It is worth noting that some of the DBPs are thermally unstable requiring that suitable precautions to be employed to avoid decomposition of the target compound(s) during analysis.

Another area of active research is in the field of pharmaceuticals, hormones, and EDCs. Unmetabolized or partially metabolized pharmaceuticals may

be introduced into wastewater systems from domestic or medical sources such as hospitals. The presence of pharmaceuticals in drinking water has been known for a number of years and reports continue to be published, the great majority since 2000. The range of pharmaceuticals detected in ground waters is considerable and includes carbamazepine, clofibrac acid, dehydroerythromycin, dichlorfenac, famethazine, ibuprofen, phenazone and metabolites, primidone, sotalol, sulfamethazine, and sulfamethoxazole. Lists for drinking water occurrences are similarly extensive. SPE followed by GC-MS and/or GC-MS-MS are the most commonly adopted methods though LC-ESI-MS-MS has also been utilized.

Concerns over the endocrine disrupting group of chemicals extend back a considerable number of years and arose over such problems as the occurrence of imposex in mollusks, mismatches between the displayed physical characteristics of fish and their genetic sex, hermaphroditism in alligators and polar bears. Recognition that many biochemically active chemicals can pass unchanged through water treatment plants has led to increased monitoring of both wastewater and drinking water. The list of chemicals with so-called endocrine disrupting properties continues to grow and includes alkyl phenols (e.g., nonyl phenol and bisphenol A), brominated fire retardants, certain chlorinated pesticides (e.g., *p,p'*-DDE, lindane) and PCBs (particularly those with *para*-hydroxy groups), dibenzodioxins and dibenzofurans, polybrominated diphenyl ethers, parabens, and phthalate esters (notably diethylhexyl phthalate). Concentrations of these compounds in waters can be ecotoxicologically significant. For example, diethylhexyl phthalate has been detected in concentrations as high as  $3.5 \text{ mg l}^{-1}$  in drinking water in Holland.

Such a variety of compounds requires the application of the full panoply of analytical techniques including ELISA, LC, LC-MS, GC-MS (negative and positive ion), GC-MS-MS. Newer methods may include online SPE systems combined with MS or UV or electrochemical detection systems. One important consideration is that analysis of a particular EDC should also include its degradation and/or metabolic products because these too may remain active. So for alkyl phenols the concurrent measurement of the appropriate alkyl phenol ethoxylates and alkyl phenoxycarboxylic acids is environmentally important and a significant analytical challenge.

Developments in chiral separations are also rapidly occurring and were the subject of a recent review by Ward. Whilst many applications utilize capillary electrophoresis, applications are also found using GC, LC, and supercritical fluid chromatography.

**Table 3** High-priority disinfection by-products (DBPs)

### General categories

Brominated DBPs

Chlorinated DBPs

Iodinated DBPs

### Specific compounds or compound groups

3-Chloro-4-(dichloromethyl)-5-hydroxy-2 (5 *H*)-furanone (MX) and its analogues ( $\geq 10$ )

Haloacetates ( $\geq 1$ )

Haloacetoneitriles ( $\geq 5$ )

Haloaldehydes ( $\geq 4$ )

Haloacids (e.g., 3,3-dichloropropionic acid)

Haloamides ( $\geq 5$ )

Haloketones

Halomethanes ( $\geq 10$ )

Halonitromethanes ( $\geq 8$ )

Nitrosodimethylamine

Nonhalogenated aldehydes and ketones ( $\geq 6$ )

Volatile organic compounds and other DBPs ( $\geq 4$ )

Chiral separations are particularly important for biologically active chiral compounds (e.g., pesticides) where the active ingredient is only one enantiomer. Chiral separations have been used to track biological degradation rates and changes in source characteristics. GC-based applications include chiral chordane and  $\alpha$ -HCH in the polar bear food chain and levetiracetam and its enantiomer in dog plasma and urine whilst LC applications include amino acids in water and chiral aroma compounds in alcoholic drinks.

There are many potential avenues of development in the field of analysis of organic compounds in water. Primary requirements will always be in the directions of greater selectivity and sensitivity and decreased analytical times. It is already clear that developments in MS technology are increasing the opportunities of near-real-time *in situ* analysis, thus providing high-quality field instruments and reducing (though probably never excluding) the need for high-quality laboratory techniques and instrumentation.

## Introduction

The biochemical oxygen demand (BOD) is a crucial environmental index for determining the relative oxygen requirements of wastewater, effluents, and polluted water. It refers to the quantity of oxygen required by bacteria and other microorganisms in the biochemical degradation and transformation of organic matter under aerobic conditions. The BOD

is also interpreted as a measure of the concentration of organic material that can serve as a substrate to support the growth of microorganisms.

The BOD test, as used for assessing the efficiency of wastewater treatment, is intended to measure some fraction of the carbonaceous oxygen demand, i.e., the oxygen consumed by heterotrophic microorganisms that utilize the organic matter of the waste in their metabolism, and not the oxygen demand exerted by autotrophic nitrifying bacteria. Since ammonia is usually present in wastewater, nitrification inhibitors must be used to suppress the exertion of nitrogenous oxygen demand. Carbonaceous oxygen demand is called first-stage BOD and nitrogenous oxygen demand is called second-stage BOD.

Chiral separations are particularly important for biologically active chiral compounds (e.g., pesticides) where the active ingredient is only one enantiomer. Chiral separations have been used to track biological degradation rates and changes in source characteristics. GC-based applications include chiral chordane and  $\alpha$ -HCH in the polar bear food chain and levetiracetam and its enantiomer in dog plasma and urine whilst LC applications include amino acids in water and chiral aroma compounds in alcoholic drinks.

There are many potential avenues of development in the field of analysis of organic compounds in water. Primary requirements will always be in the directions of greater selectivity and sensitivity and decreased analytical times. It is already clear that developments in MS technology are increasing the opportunities of near-real-time *in situ* analysis, thus providing high-quality field instruments and reducing (though probably never excluding) the need for high-quality laboratory techniques and instrumentation.

## Biochemical Oxygen Demand

**R Kumar and A Kumar**, Institute of Genomics and Integrative Biology, New Delhi, India

© 2005, Elsevier Ltd. All Rights Reserved.

This article is a revision of the previous-edition article by C P Way, pp. 5527–5533, © 1995, Elsevier Ltd.

## Introduction

The biochemical oxygen demand (BOD) is a crucial environmental index for determining the relative oxygen requirements of wastewater, effluents, and polluted water. It refers to the quantity of oxygen required by bacteria and other microorganisms in the biochemical degradation and transformation of organic matter under aerobic conditions. The BOD

is also interpreted as a measure of the concentration of organic material that can serve as a substrate to support the growth of microorganisms.

The BOD test, as used for assessing the efficiency of wastewater treatment, is intended to measure some fraction of the carbonaceous oxygen demand, i.e., the oxygen consumed by heterotrophic microorganisms that utilize the organic matter of the waste in their metabolism, and not the oxygen demand exerted by autotrophic nitrifying bacteria. Since ammonia is usually present in wastewater, nitrification inhibitors must be used to suppress the exertion of nitrogenous oxygen demand. Carbonaceous oxygen demand is called first-stage BOD and nitrogenous oxygen demand is called second-stage BOD.

Some other methods have also been developed to estimate the water pollution potential. The chemical oxygen demand (COD) test was developed because a BOD<sub>5</sub> test requires 5 days for completion and therefore is not suitable either for real-time evaluation of the efficiency of wastewater treatment or for operational control of the treatment processes. The total organic carbon (TOC), dissolved organic carbon (DOC), and the ultraviolet spectrophotometric absorption (at 254 nm) methods for determining dissolved organic material and volatile suspended solids of particulate organic material were developed as alternative methods for measuring the strength of wastewater on the basis of an assumption that the primary purpose of biological treatment is to reduce the concentration of organic material in wastewater.

## History

The development of the field of environmental engineering science has been dependent on the development of the BOD concept and test. The names of Phelps, Streeter, and Butterfield are prominent in the development of the BOD concept. The primary interest of these early workers was to determine the dissolved oxygen (DO) profile in the receiving stream in response to a known dilution of wastewater. The interest was in determining the capacity of the receiving stream to assimilate organic wastes.

The modern concept of the BOD test originated in 1884 when Dupre showed that microorganisms, in metabolizing organic matter, caused a decrease in the DO levels of incubated water samples. Established in 1898, the United Kingdom Royal Commission on Sewage Disposal issued nine reports, the eighth of which formalized BOD to a standardized test in 1913. It recommended 5 days as the standard incubation period for microorganisms to act on organic matter for several reasons.

First, this period was long enough to allow a significant amount of organic material to oxidize but shorter than the time required to initiate significant oxygen consumption by oxidation of ammonia to nitrate (nitrification). Second, as it reflected the likely maximum time for water in any British river to flow to the sea, the effect of organic material on oxygen levels would be limited to that period before the water underwent high dilutions with seawater.

The present standard condition of 20°C was incorporated into the BOD method by the American Public Health Association Standard Method Committee in 1936 in the eighth edition of *Standard Methods for the Examination of Water and Wastewater*.

## Concept and Definition

Prediction of the rate of consumption of DO by microorganisms in a body of water receiving effluents is an essential part of assessing the potential for deoxygenation of the receiving water. The original approach to making this assertion (developed ~100 years ago) was to measure the DO concentration in the receiving water, incubate a sample of the water sealed off from contact with sources of oxygen for a period of time, and then measure the DO remaining to find out how much had been consumed. This approach evolved into the BOD<sub>5</sub> test, which has been in use in more or less its present form for more than 60 years.

The BOD test is a bioassay run under standardized laboratory conditions of time, and temperature and controlled conditions of pH, dilution, nutrients and microorganisms. Complete oxidation of organic matter can take anything from 20 days to several months, but because quantification of the amount of oxygen involved is impractical as a standard laboratory test, the shorter time span of 5 days was chosen (though some analysts use 7, 3, or even 2 days). The number of days over which the BOD test is carried out is often designated by using a subscript, e.g., BOD<sub>5</sub>. Some seeding material (bacteria) from the waste treatment plant in the form of settled sewage or ready-made commercially available material is used in the test.

## Expected Variance

This method involves microorganisms, which might not be specific to a particular wastewater. One might well ask whether a low value of BOD would mean that the organic substrate had been eaten up or simply that the seed cells could not metabolize it.

'Standard Methods', using results from a series of interlaboratory studies, indicates as acceptable a range of  $\pm 15\%$  at the  $200 \text{ mg l}^{-1}$  level for the reference glucose-glutamic acid solution. While variances quoted for real samples range up to 50%, replication of real samples by a single analyst should in general produce results within 15% around the mean.

## Sampling and Sample Storage

Samples for BOD analysis may degrade significantly during storage between collection and analysis. One must consider the following for proper sampling and storage.

- Any source of organic contamination that could contribute a significant fraction to the measured

BOD load, e.g., detergent residues in a sample container, especially for low-BOD samples.

- Any loss of organic material that would be a significant fraction of the BOD load: e.g., where the use of plastic containers could result in the diffusion of significant amounts of organic material into the walls of the container, a glass container should be used instead.
- Collection of a representative sample; as BOD tests are often carried out on sewage effluents and wastewater that are likely to be inhomogeneous, care should be taken to ensure the sample is as representative as possible.
- Sample volume for low-BOD samples (e.g., 0–6 mg l<sup>-1</sup> level); a sample volume of at least 1 l is required for the standard test.

No chemical preservation processes can be used on samples requiring a BOD test as these would affect the microorganisms involved. Since any bacterial action on organic waste can be expected to continue after collection of a sample, there could be a significant decrease in BOD values between collection and analysis, depending on the time involved, the organic substrate, and the vigor of the organisms. Hence it is generally recommended that analysis should begin within 2 h of collection. Chilling the sample to 4°C or lower (but not freezing) will slow bacterial action. With chilling, analysis should begin within 6 h and not exceed 24 h. Results with length and temperature of storage are then reported.

For composite samples (e.g., from automatic samplers), additional requirements include limiting the composting period to 24 h and noting the storage time, starting from the end of the composting period, while following the above recommendations for starting analysis and recording temperature and time of storage.

These recommendations are designed to produce a standardized test. It should be noted, however, that there may be a significant decrease in BOD for some very easily degraded wastes (e.g., those containing a high proportion of the organic material as sugar may degrade significantly in 24 h even with chilling). Conversely, waste with a BOD value in the high hundreds or thousands of milligrams per liter in a completely filled airtight container is likely to degrade very little over several days because it has become anaerobic.

Freezing has been proposed as a preservation technique for BOD samples to kill or inactivate microorganisms. While some researchers have found that this gives lower BOD values when compared with BOD analyses carried out soon after sampling, others have noted no significant change. The adaptation of

microorganisms to the organic material and the number of organisms are the factors that influence BOD results, and freezing and reseeded after thawing may change either or both of these.

## Techniques – Standard Procedures

Standard laboratory safety procedures must be followed since many of the chemicals are toxic or hazardous.

Briefly, any chlorine is removed from a water sample to be tested and the sample or a diluted version of it is adjusted to approximately pH 7. The pH buffer and nutrients are added along with a seed and/or nitrification inhibitor if necessary. Two BOD bottles are filled to an extent such that insertion of the stoppers displaces all the air. The initial DO level (DO<sub>i</sub>) of the first bottle is determined using the Winkler titration method (a titrimetric determination) or using one of the modifications of this method (most commonly the azide modification). The second bottle is then incubated for 5 days, at which time the DO level (DO<sub>f</sub>) is determined:

$$\text{BOD} = (\text{DO}_i - \text{DO}_f - \text{seed contribution}) \times \text{dilution factor} \quad [1]$$

where seed contribution = ((volume (ml) of seed added in BOD bottle)/(volume (ml) of BOD bottle)) × BOD of seed.

Only one bottle will be needed for DO<sub>i</sub> and DO<sub>f</sub> if a DO electrode is used. If replicate determinations are carried out, it is customary to carry out a single determination on the initial DO bottle and have replicates for the final DO determinations, which are subject to greater variation; i.e., for Winkler titration determination of DO, three bottles are prepared, one used immediately for DO<sub>i</sub> and the other two incubated and used for DO<sub>f</sub> determination.

Common sources of error are discussed below.

Dirty BOD bottles produce unreliable results, and so residues such as protein, oil, and grease from previous samples and detergent from cleaning of the BOD bottle must be removed.

Water used in the dilution of samples can cause error when copper, forming part of a water distillation unit, contaminates the distilled water, poisoning the microorganisms.

Another possible source of error is organic leachates from deionizing resins. Theoretically these could lead to a positive error in BOD results, but in practice they can lead to low results by poisoning the bacteria. Leachate problems are most likely to occur when

new resins have been installed in a deionizing unit. High-purity water units with organic scrubber cartridges will help solve this problem, but contamination from this source cannot be ruled out completely as cartridges can be overloaded. Standard Methods sets a limit of less than  $0.2 \text{ mg l}^{-1}$  oxygen demand for dilution of water over the 5 day incubation period.

Some likely sources of contamination are biological growths in plastic tubing attached to distillation or deionizing resin units; the deionizing resin units themselves; nutrient containers, especially the buffer solution container; and the storage containers. As far as possible, plastic tubing and storage containers should be replaced by glass equivalents for dilution water.

The presence of chlorine in a sample will cause an error by killing BOD microorganisms. Chlorine can be detected by odor, or by using a sample chlorine water chemistry test kit ( $0.1 \text{ mg l}^{-1}$  reporting limit). Samples will require seeding after dechlorination, as will any samples disinfected by other means.

In filling the BOD bottle with the sample, care is needed to exclude air bubbles, which contribute a nonreproducible source of oxygen to the test; these can be dislodged by tapping the bottle carefully. As 1 ml of air in a 300 ml BOD bottle contributes  $\sim 1 \text{ mg l}^{-1}$  to a DO determination, tiny air bubbles that may be difficult to dislodge and have total volume less than 0.1 ml may be ignored. The pointed end of the ground-glass stopper on a standard BOD bottle minimizes the risk of trapped air.

Samples with DO levels above  $9.2 \text{ mg l}^{-1}$  at  $20^\circ\text{C}$  (i.e., supersaturated with air) may be found. These high levels can be caused by higher DO levels in cold waters that are brought up to  $20^\circ\text{C}$  or through photosynthesis. The samples should be adjusted to  $\sim 9 \text{ mg l}^{-1}$  by aeration at  $20^\circ\text{C}$ .

Some preliminary treatment of the sample may be required.

Where large particulate material is present, it is often difficult to obtain a representative sample. A decision on whether a high-speed blender should be used to produce a more homogeneous sample can only be made after due consideration of the degree of change that the blending will have on the BOD result. Organic particulates contribute to BOD but generally to a smaller degree than dissolved organic material. Thus, while finer organic particles produced by blending are likely to lead to a higher BOD, the degree of increase is likely to be small when viewed in the context of BOD contributions of dissolved and particulate organics. But this may not be true in some cases.

One preliminary treatment of the sample is the addition of a nitrification inhibitor. That suggested

by Standard Methods is 3 mg of 2-chloro-6-(trichloromethyl)pyridine per 300 ml BOD bottle. An alternative inhibitor is *N*-allyl thiourea, added at the rate of  $0.5 \text{ mg l}^{-1}$ .

It is often necessary to add a seed to samples, and seed microorganisms are available from a number of sources, e.g., settled sewage, the wastewater itself, or soil. A new commercial product is dehydrated microbial seed, which contains a mixture of microorganisms and is suitable for most types of domestic and industrial wastewater. As the general recommendation is that fresh seed be prepared for each working day, allowance must be made for the rehydration time. Some products have a recommended rehydration time of 1 h, while others require overnight rehydration. The advantages of the manufactured dehydrated seed over other sources are convenience, greater reproducibility of BOD results, less variance of seed quality with time, and greater likelihood of a high concentration of viable bacterial species.

For all sources of seed (including the manufactured seed) the possibility exists that some wastes will cause poisoning of the microorganisms. Some wastes will have developed microorganisms adapted to the toxic conditions and hence give expected BOD results, but in other wastes the microorganisms will adapt over the period of the BOD test. Because of the lag time involved in adaptation, a lower BOD is obtained than might be expected. If the toxicity is sufficiently acute, a zero or close-to-zero result is obtained.

In BOD dilutions, the following factors must be considered.

Since air-saturated freshwater at sea level and at a temperature of  $20^\circ\text{C}$  contains  $9.1\text{--}9.2 \text{ mg l}^{-1}$  oxygen, samples with BOD levels above  $6\text{--}7 \text{ mg l}^{-1}$  will require dilution (this assumes that the  $\text{DO}_i$  is  $8 \text{ mg l}^{-1}$  or higher).

Dilutions resulting in a residual DO level of at least  $1 \text{ mg l}^{-1}$  and a DO uptake of at least  $2 \text{ mg l}^{-1}$  after the 5 day incubation produce the most reliable results. Hence a single dilution ( $n$  times) will cover a BOD range of  $n$  times ( $2\text{--}7.5 \text{ mg l}^{-1}$ ), if  $\text{DO}_i$  level is  $8.5 \text{ mg l}^{-1}$ .

Dilutions are based on past experience, visual inspection and odor, published suggestions (Table 1), and they are made when using a more rapid technique such as COD. In almost all cases several dilutions are made. Dilution increments of two to three times (e.g., a sample is diluted 8 times, 20 times, 50 times, 125 times) ensure that the various BOD ranges covered by the different dilutions will overlap. Some laboratories estimate the BOD of a given sample and make four, five, or more dilutions to cover BOD levels lower and higher than their estimate. Higher COD results (greater than  $200 \text{ mg l}^{-1}$ ) can be used reliably for calculating appropriate dilutions for the

**Table 1** Suggested dilutions for various waters

	<i>Expected BOD level (mg l<sup>-1</sup>)</i>	<i>Suggested dilution range</i>
Unpolluted river water	0–3	Undiluted
Polluted river waters	5–10	Undiluted to four times
Biologically treated effluent	15–30	4–20 times
Raw and settled wastewater	80–400	20–100 times
Strong industrial wastes	Highly variable <sup>a</sup>	100 times and higher

<sup>a</sup>A COD or other indicative determination is recommended to establish a possible range.

OD test. Two dilutions will be sufficient:

$$\text{higher dilution} = \text{COD}/7 \quad [2]$$

(e.g., COD = 700 mg l<sup>-1</sup>, higher dilution = 100×)

$$\text{lower dilution} = \text{COD}/20 \quad [3]$$

(e.g., lower dilution = (700 mg l<sup>-1</sup>)/20 = 35×).

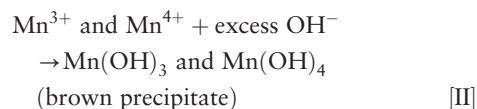

An appreciation that COD can oxidize some inorganic materials and microbially resistant organic materials as well as material oxidized in the BOD process is needed for successful application of the calculation; e.g., coal particles will give a high COD but low BOD.

If a low dilution of less than 10 times is made from a high- or moderately high-BOD sample, the initial DO is likely to be low (less than 8 mg l<sup>-1</sup>). This results from an almost zero sample DO with dilution water having ~9 mg l<sup>-1</sup> DO. A quick calculation with the above assumptions gives some indication of the DO level to be expected. The diluted sample should be aerated to raise the initial DO. The above implies that a higher dilution may be needed since a zero or near-zero DO in the sample suggests the likelihood of a moderately high BOD (though the presence of a chemical reductant or other causes cannot be ruled out).

### The Winkler Titration Method

The classical method for DO determination is the Winkler titration method, which is still frequently used as a reference procedure for calibration of DO meters. It is inexpensive in capital cost outlay, requiring only common laboratory glassware (burettes, pipettes, measuring cylinders, conical flasks, volumetric flasks), burette stands, wash bottles, and chemicals. The principal reactions involved are

shown in reactions [I] and [II]:

Excess Mn<sup>2+</sup> undergoes reaction [III]:

If the sample is devoid of oxygen at the end of the incubation period, this step in the determination will show a white precipitate. Precipitates ranging from light brown to dark brown indicate low to high oxygen levels. Manganese hydroxide precipitates settle out much more slowly in seawater than in lower-density freshwater.

The second stage of the determination is shown in reaction [IV]:

Iodine is produced in stoichiometric amounts dependent on the amount of Mn(OH)<sub>3</sub> and Mn(OH)<sub>4</sub> present.

Iodine is then titrated with sodium thiosulfate (or the more stable, but poisonous, phenylarsenic(III) oxide (phenylarsine oxide)) using starch as the indicator (reaction [V]):

The starch and iodine form a blue complex. The solution becomes colorless when all the iodine has been reduced to iodide by the thiosulfate. The iodine formed in reaction [IV] will range from a strong yellow color (indicating a high level of oxygen) to a dark brown precipitate from reaction [II] to no iodine (colorless solution), corresponding to zero oxygen.

Aids for BOD determination include syringe-type dispensers for the manganese(II) salt and other solutions, and commercially available digital burettes, which are more convenient than the conventional glass-type ones.

### The Oxygen Membrane Electrode

This is a well-established standard procedure for measuring DO levels. Generally the determination depends on oxygen diffusing through a membrane to an electrode, where it undergoes an electrolytic reduction (by galvanic action or by polarographic

action). The potential or current involved in this is proportional to the rate of oxygen diffusing through the membrane, which in turn depends on the dissolved oxygen concentration in the sample.

There are some practical considerations here. The most suitable DO meters have oxygen probes shaped to fit a standard BOD bottle, or include an adaptor (a funnel) that prevents loss of the sample when the oxygen probe is inserted into the BOD bottle.

In general, electrodes consume oxygen as part of the measuring procedure, but as long as the measuring time does not exceed 1 or 2 min in a 300 ml bottle, this will not affect the results significantly. The rate of oxygen depletion depends on the design and the type of electrode (galvanic or polarographic).

Since most electrodes rely on the rate of oxygen diffusing to the inside of the membrane being proportional to the concentration of oxygen on the sample side of the membrane, anything fouling the membrane, such as oil and grease, will cause a low reading. An air bubble swirling on the membrane or damage to the membrane will also produce an erratic reading. In practice, if the BOD dilutions are close to correct, fouling is rarely a problem.

Since the electrodes consume oxygen, localized depletion of oxygen occurs near the membrane. To overcome this, some BOD oxygen probes have built-in stirrers. Other probes require a stirrer bar and an external magnetic motor.

The sensor design consumes oxygen at the cathode like conventional oxygen probes but produces an equivalent amount of oxygen electrolytically at the anode. When these concentrations are equal there is no net consumption of oxygen, but electrolysis proportional to oxygen concentration is still occurring and hence is a measure of the DO. Hence the results are not affected even over prolonged testing. Anything short of complete fouling of the membrane does not affect the final DO reading but does lengthen the time required to reach it.

An advantage of the oxygen probe is that it enables the DO levels to be read before the end of the 5 day period.

For both these methods – Winkler titration and the DO meter method – suspended and settled particulate organic material also contribute significantly to the BOD, though not as readily as dissolved organic matter. In cases where settled material forms a thick layer, dilution allows greater access of the bacteria to the settled material by making more surface area of the material available.

The ratio of the various species of bacteria normally encountered can change in a 5 day period. The BOD is the result of a summation of the oxygen demand of these microorganisms, whose contribution

**Figure 1** Example of S-type curve indicating moderate toxicity, insufficient bacteria, or bacteria acclimatizing to sample.

to the oxygen demand will change with time because of the changing population (implying a possible change in overall reaction rate) and changing feedstock (both in amount and material as it is acted on by bacteria). A well-documented example of the bacterial population changing with time is the increasing presence of nitrifying bacteria in sewage samples.

Material toxic to microorganisms will cause zero BOD results. At sufficiently high dilutions, toxic materials will no longer inhibit microorganisms. The intermediate situation produces increasing BOD results for increasing dilutions. If this is observed, it is often taken to mean that there is toxic material present. There can, however, be other explanations, such as more readily available feedstock or a better food-to-bacteria ratio. Where there is a dramatic change in results with increasing dilutions, such as a 100% increase, the most likely explanation will be the presence of toxic materials.

Another indication of toxic effects can be seen if the oxygen demand is monitored on a daily or more frequent basis. An S-type curve could indicate toxicity (Figure 1). A similar curve also results from a low population of suitable microorganisms for a particular sample. In both cases the 'S' shape is derived from the organisms adapting and increasing in population over a period of 1–3 days.

## Techniques – BOD Biosensor

The conventional BOD test has certain benefits such as being a universal method of measuring most wastewater samples, and furthermore, no expensive equipment is needed. It has, however, the limitation of being time consuming, and consequently it is not suitable for online process monitoring. Thus, it is necessary to develop a measurement method that could circumvent the weaknesses of the conventional method. The need for fast, portable, and cost-effective methods for environmental monitoring has stimulated the development of a variety of field analytical tools such as biosensors. Biosensors are

devices that transduce a selective biochemical response to a measurable signal. Several biosensor methods for BOD measurement have been developed. The first report of a BOD biosensor was published by Karube *et al.* in 1977. After that, several kinds of microbial BOD sensor have been developed, and various modifications have been carried out (Table 2). Most of the BOD sensors referred to above consisted of a synthetic membrane with a single or a random combination of immobilized microorganisms serving as a biocatalyst. A rapid and reliable BOD sensor should be capable of analyzing a sample of complex constituents with relatively low selectivity. Thus, the sensor should respond to all kinds of biodegradable organic solutes in the samples. It is also important that the sensor should give results comparable with those obtained using the conventional BOD method.

Most of the previously reported BOD sensors are biofilm-type whole cell-based microbial sensors, which rely on measuring the bacterial respiration rate in close proximity to a suitable transducer. A common feature of these sensors is that they consist of a microbial film sandwiched between a porous cellulose membrane and a permeable membrane as the biological recognition element. This microbial film is an immobilized microbial population that can biooxidize the organic substrate to be quantified. The response is usually a change in concentration of the DO or other phenomena such as light emission. A physical transducer is used to monitor this process. The result is a change in an electrical or optical signal. The signal is amplified and correlated to the content of biodegradable material present.

A biofilm sensor for BOD consists of a DO probe such as an oxygen-permeable membrane, with another membrane containing bacteria (the biofilm) between the membrane and the sample (Figure 2). Organic material diffuses into the biofilm where the bacteria act on it, causing a drop in oxygen levels that is measured by the probe. The probe is calibrated by setting a baseline level ('zeroing') with a solution containing no organic material, followed by measuring the steady-state response in a solution of known BOD – normally 150 mg glucose plus 150 mg glutamic acid in 1 l of distilled water taken as  $\sim 200 \text{ mg l}^{-1}$  BOD. The response of unknown samples is compared with the standard to obtain the BOD result. The times quoted to reach a steady reading vary from under 10 to 30 min.

A related technique utilizing a fluidized bed (in place of the biofilm) with DO probes has been incorporated into a commercially available instrument.

Another method uses a biofilm as in the previous method, but instead of waiting for a steady-state

reading, it measures the rate of change of oxygen uptake by the bacteria, obtaining results in  $\sim 1$  min.

These methods are similar to a BOD test, using bacterial activity for their measurement and consequently responding strongly to easily biodegradable material. Many researchers use a monoculture; how well this approximates a mixed culture's response will depend mainly on the sample. Some researchers have had trouble obtaining reproducible results from sensors that use mixed microorganisms from activated sludge.

Apart from the effects of dilution on BOD, biofilm sensors cannot include degradation of organic particulate matter to any significant extent since the bacteria are immobilized within the sensor system. It has been shown, however, that biofilms can be acclimatized to different substrates (wastewater as well as pure compounds) to give improved responses.

For low-BOD samples, the kinetic mode has not been shown to be as sensitive as either of the conventional BOD methods or the steady-state biofilm method. Both biosensor techniques share with oxygen electrodes the danger of fouling of the biosensor membrane with oil. Because biofilm techniques allow rapid process control, they are most likely to find application in monitoring a consistent organic process waste.

Because of the importance of biofilm technology in waste processing, it is likely that the research into it will carry over to BOD biofilm sensors.

A comparison of the processes involved in the Winkler titration and DO meter methods with alternative methods illustrates situations where they may not produce equivalent results. For example, where oil and grease are present in water, dilution allows greater accessibility by bacteria owing to the presence of finer oil droplets. In this case a higher BOD result is obtained using the Winkler and DO methods than is obtained by the lower-dilution manometric methods.

## Techniques – Other Procedures

How well a particular alternative technique approximates the BOD test for a given sample will determine how successful the alternative technique is in providing BOD results. And although an alternative technique may not give the same result as a conventional BOD test, it can provide information that may be more appropriate.

While the above methods are the most commonly used for BOD determination, there are two commercially available alternatives based on supplying extra oxygen from an airspace above a sample or oxygen

produced electrolytically, and there are two biofilm techniques that are not commercially available. Two other developments based on the conventional techniques – robotics and a graphical method for determining BOD – are discussed.

#### **Manometric Method – Oxygen from Airspace above Sample**

In this method a manometer reads the pressure of the airspace, isolated from the atmosphere, above the sample or diluted sample to be tested. Agitation keeps the sample supplied with oxygen from the airspace, and carbon dioxide is removed by absorption in potassium hydroxide solution. The manometer measures the pressure drop in the vessel caused by the consumption of oxygen in the BOD process. As the amount of oxygen available from the airspace is considerably higher than that available from the water, the BOD range covered by a single dilution is commensurately higher (one manufacturer quotes a range of 0–350 mg l<sup>-1</sup> without dilution).

Different BOD ranges can easily be set by changing the amount of sample (and hence the sample-to-air ratio) in the vessel. The manufacturers' recommended minimum and maximum volumes of a diluted sample set the BOD range. The minimum sample volume (giving the highest range) is not always appropriate as it causes a loss in resolution.

An advantage of this system over the conventional BOD system (Winkler titration method) and the DO probe is that it can be used to monitor changes in DO levels with time. The procedures for ensuring that sufficient nutrients are available for the 5 days of the tests are not as rigorous as with the standard procedures, however, and this could lead to low BOD results. Additionally, air could leak into the manometer system, causing errors.

A further disadvantage is the limitation on the number of samples that can be processed at any time unless multiple units are purchased.

#### **Manometric Method – Oxygen Supplied Amperometrically**

This is similar in essence to the manometric method discussed above. A sample vessel is fitted with a manometric switch and an electrolytic oxygen generator. As oxygen is consumed by microorganisms and carbon dioxide is removed by potassium hydroxide, a drop in pressure occurs and the manometer triggers production of oxygen to replace the oxygen consumed. The amount of electricity used to generate the oxygen is measured and is proportional to the BOD. The advantages of this method over all the preceding methods are that an even greater BOD range can be achieved before dilution is needed and that the system can be adapted easily for continuous monitoring or readings at fixed time intervals. For one of the commercially available instruments a specification of 60 mg O<sub>2</sub> per hour maximum demand is given. On the assumption that the oxygen demand follows an approximately first order-type curve for the 5 days of the test, the above specification would mean that dilutions would be needed when the BOD<sub>5</sub> levels reach the thousands of milligrams per liter range.

This system has the same advantages and disadvantages as the first manometer method discussed. For both, the comments relating to the effect that dilution can have on a BOD result are appropriate.

#### **Robotics**

The most persistent criticisms of the BOD test are that it is time consuming and labor intensive. In response to the latter claim, laboratories and instrument manufacturers have developed BOD robotic

systems using DO meters for reading the initial and final DO levels. The most likely sources of error from the robotic system are nonrepresentative aliquots of samples and failure to detect bubbles trapped beneath the sensor. As the robotic systems are not yet as reliable as autosamplers, some manual intervention is generally needed.

### Graphical Method

The BOD can be determined graphically by having a close range of dilutions to produce a graph of DO ( $\text{mg l}^{-1}$ ) remaining versus volume of sample in the BOD bottle, i.e., volume of sample (ml) diluted to 300 ml:

$$\text{BOD} = -300 \times \text{slope} - y \text{ intercept} + S \quad [4]$$

where 'slope' is the slope of the best-fitting straight line of the above plot, the  $y$  intercept is the  $y$  intercept of the best-fitting straight line of the above plot, and  $S$  is the DO ( $\text{mg l}^{-1}$ ) of the undiluted sample.

With good quality data the method is capable of a better blank and seed correction than that of the calculation procedure of Standard Methods. It can also make redundant the determination of  $\text{DO}_i$ . With this method dilution water that does not meet the Standard Methods criterion of having a demand not more than  $0.2 \text{ mg l}^{-1}$  over the 5 day incubation period can still be used. With the close dilutions used acting as surrogate replicates, this offers reassurance that BOD results are correct. Similar assurance is, however, gained from two or more dilutions and replication in the conventional BOD procedure.

The graphical method does not take into account that there may be oxygen-consuming compounds present that give zero sample DO and consume oxygen from the dilution water, i.e.,  $S$  may effectively be less than zero.

If there is a scatter of points in the plot, some bias in the slope may occur, producing bias in the BOD result. A large number of dilutions are required for the graphical BOD procedure.

### Applications

The BOD test has traditionally been used to measure waste loadings ahead of and after a sewage treatment works or waste-processing plant to determine the efficiency of their biological treatment. It is one of the important criteria used in the design of organic waste treatment plants and is used in the assessment of polluted waters and wastewater. More recently it has been used in government regulatory control of pollution and disposal of water.

As a biological test it is likely to give a more meaningful indication of the impact of waste on oxygen levels in a stream or river than will a purely

chemical test and is therefore an important water quality parameter.

Although it has been used in process control, the time delay makes it less efficient than alternative methods.

## Chemical Oxygen Demand

**Z Hu**, Cornell University, Ithaca, NY, USA

### Introduction

In addition to biochemical oxygen demand (BOD), chemical oxygen demand (COD) is widely used as a surrogate measure for carbon bioavailability. Compared to the BOD test, which requires days, the COD test is designed to yield results in a much shorter time (within hours). The COD test uses strong oxidants to oxidize organic matter that microorganisms may oxidize only partially or not at all. The sample COD is finally calculated by comparing with standards that are typically used, e.g., phthalate, oxalate, and glucose. In this article, standard reflux methods with dichromate digestion are reported, although determination of COD based on permanganate index is still in practice for natural waters. Due to some limitations and disadvantages of the standard methods, other modified methods are also presented. These include: the replacement of hexavalent chromium, mercury, and silver metals; microwave digestion; automation and online COD measurement; and electrochemical oxidation to measure the sample COD. Determination of the colloidal COD fraction is also discussed and applications of COD tests are presented in light of water and wastewater analysis.

### Background

COD is defined as the amount of oxygen equivalents consumed in the chemical oxidation of organic matter by strong oxidant (e.g., potassium dichromate). The COD test consists of refluxing a sample for 2 h in the presence of a known amount of oxidant. The concentration of organic matter in terms of oxygen equivalents can be determined from the difference of initial and remaining oxidant concentrations in the sample.

Most organic matter can be oxidized by strong oxidants, although straight chain carboxylic acids may not be oxidized in the absence of a silver sulfate catalyst. Silver sulfate is, therefore, added during COD tests to facilitate the complete oxidation. However, the chloride ion, a common aqueous constituent, reacts with silver ions to precipitate silver chloride, and thus eliminates the catalytic activity of silver yielding a negative interference. Alternatively, chloride, bromide, or iodide can react with dichromate

to produce the elemental form of the halogen, yielding an overestimate of COD. Hence, mercury sulfate is added to minimize reaction interference.

Both organic and inorganic components are oxidized during COD tests. If only the COD associated with the organic component is desired, provisions need to be made to eliminate contributions from oxidation of inorganic components. For instance, chloride interference is removed by  $\text{Hg}^{2+}$  complexing of  $\text{Cl}^-$ . Corrections for chloride interference vary as elemental chlorine may react with ammonia and its derivatives in the sample even though ammonia and its derivatives are not oxidized. Nitrite ( $\text{NO}_2^-$ ) has a COD of  $1.1 \text{ mg O}_2 \text{ mg}^{-1} \text{ NO}_2^- \text{-N}$ . To eliminate its interference, nitrite is converted by sulfamic acid with the addition of 10 mg sulfamic acid for each milligram  $\text{NO}_2^- \text{-N}$  present in the sample. Finally, separate determinations of other reduced inorganic species (e.g., ferrous iron and sulfide) are needed if the samples contain significant levels of these ions. Stoichiometric oxidation of the known reduced inorganic species can be assumed and corresponding corrections are made.

### Sampling

Samples are commonly stored in glass bottles, although it is still possible for a trace of organic matter to sorb to the glassware. A standard sample preparation practice to avoid trace organic contamination may, therefore, apply by baking out glass bottles at  $400^\circ\text{C}$  for at least 1 h. If a sample contains significant amount of particulates, it should be blended first in order to obtain a representative aliquot. All samples should be analyzed as soon as possible. If delay is unavoidable, samples may be stored by acidification to  $\text{pH} \leq 2$  with concentrated sulfuric acid.

If only the soluble COD is desired, the sample should be coagulated with lanthanum chloride ( $\text{LaCl}_3$ ) and filtered through a  $0.45 \mu\text{m}$  membrane to eliminate colloidal and particulate fractions. The filtrate can then be subjected to standard COD analyses.

### Standard Methods

Most types of organic matter (electron donor) are oxidized to carbon dioxide and water by boiling a mixture of dichromate and sulfuric acid. Samples are refluxed in a strong acid with a known excess of potassium dichromate ( $\text{K}_2\text{Cr}_2\text{O}_7$ ). Dichromate ( $\text{Cr}^{6+}$ , orange color) is reduced to chromate ( $\text{Cr}^{3+}$ , green

color) via the following reaction:

By using a titrimetric method, the remaining dichromate is back-titrated with ammonium iron(II) sulfate (ferrous ammonium sulfate (FAS)) to determine the amount of  $\text{Cr}_2\text{O}_7^{2-}$  consumed:

The amount of oxidized organic matter is calculated in terms of oxygen equivalents (1 equivalent weight electron equals 8 g of oxygen) with the following equation:

$$\text{COD as mg O}_2 \text{ l}^{-1} = (A - B) \times M \times 8000/V \quad [3]$$

where A = FAS used for blank (ml), B = FAS used for sample (ml), M = molarity of FAS, and V = sample volume (ml).

By using a colorimetric method, the formation of  $\text{Cr}^{3+}$  (green color) is quantified as the oxidation proceeds and the absorbance is read at 600 nm. Alternatively, the disappearance of the orange  $\text{Cr}_2\text{O}_7^{2-}$  can be determined at 420 nm. The sample COD is determined colorimetrically at 600 and 420 nm, respectively, based on standard COD calibration curves.

Most organic compounds are oxidized with the dichromate reflux method under standard procedure, but ammonia and organic nitrogen are not oxidized by dichromate in the absence of significant concentration of elemental chlorine. Hence, the dichromate reflux method is preferred over procedures using other oxidants because of its superior oxidation ability. There are, however, several potential sources of limitation in the test including the following:

- Pyridine and related aromatic compounds resist oxidation.
- Straight chain aliphatic compounds are not oxidized in the absence of  $\text{AgSO}_4$  and may not be completely destroyed even in the presence of  $\text{AgSO}_4$ .
- Volatile organic compounds may escape and are oxidized only to the extent that they remain in contact with the oxidant.

### Open Reflux Method

For an open reflux method, the standard procedure follows: pipette 50 ml sample (for samples with COD higher than  $900 \text{ mg O}_2 \text{ l}^{-1}$ , use a small sample portion diluted to 50 ml) in a 500 ml refluxing flask. Add 1 g  $\text{HgSO}_4$ , and glass beads. Slowly add 5 ml sulfuric acid–silver sulfate mixture (10–15 g  $\text{Ag}_2\text{SO}_4$  per

milliliter concentrated  $\text{H}_2\text{SO}_4$ ) while gently mixing to dissolve use  $\text{HgSO}_4$  and avoid possible loss of volatile organic components. Add 25.00 ml of  $0.0417 \text{ mol l}^{-1} \text{ K}_2\text{Cr}_2\text{O}_7$  and mix. Attach the flask to a condenser and turn on cooling water. While continuously stirring, add the remaining 70 ml sulfuric acid–silver sulfate mixture through the open end of the condenser. Heat the sample for 2 h in the flask under reflux conditions. Wash down the condenser with de-ionized (DI) water into the flask and cool to room temperature. Titrate excess  $\text{K}_2\text{Cr}_2\text{O}_7$  with standard  $0.25 \text{ mol l}^{-1}$  FAS using two to three drops ferroin indicator to determine the volume of FAS utilized. Acquire a blank sample (50 ml DI water) through the same procedure to determine the value of A. For quality assurance and quality control purpose, conduct a test on a standard potassium hydrogenphthalate (KHP) solution ( $500 \text{ mg O}_2 \text{ l}^{-1}$ ).

The above procedure is suitable for a sample with a COD in the range of 0–900  $\text{mg O}_2 \text{ l}^{-1}$ . For high COD ( $> 1000 \text{ mg O}_2 \text{ l}^{-1}$ ) samples, dilution may be necessary. Selection of a dilution ratio can be determined from the color after mixing the sample with dichromate and sulfuric acid. If the sample solution becomes bluish green or green within a few minutes, a 10-fold dilution is suggested. Solutions showing predominantly orange color with little change within minutes should not require dilution.

For low COD ( $< 50 \text{ mg O}_2 \text{ l}^{-1}$ ) samples, the standard procedure is still valid by using dichromate and FAS at 1/10 the concentration given above (i.e.,  $0.00417 \text{ mol l}^{-1} \text{ K}_2\text{Cr}_2\text{O}_7$  and  $0.025 \text{ mol l}^{-1}$  FAS). Great care must be taken with this procedure because even slight contamination of organic compounds on glassware can lead to significant error. If a further increase of sensitivity is required, a large volume of sample may be concentrated to 150 ml (equivalent to the total volume in the standard procedure) after the addition of all reagents by boiling in the refluxing flask open to the atmosphere without the condenser attached. Before refluxing, the amount of chloride must be determined in order to add sufficient  $\text{HgSO}_4$  on the basis of a weight ratio of 10:1 for  $\text{HgSO}_4:\text{Cl}^-$ . A blank should be carried out through the same procedure. Compared to ordinary evaporative concentration methods, this technique has the advantage of reducing losses of easily digested volatile organic compounds.

### Closed Reflux Methods

Compared to the open reflux method, volatile organic compounds are more easily oxidized with closed reflux methods, because those compounds remain in contact with the oxidant in closed vessels.

Furthermore, closed reflux methods are preferred because fewer reagents are used, and therefore less hazardous wastes are generated. The methods are equivalent to ISO 15705–Determination of the chemical oxygen demand index (ST-COD) – Small-scale sealed-tube method.

**Closed reflux: titrimetric method** The procedure is a scaled-down adaptation from the one described above with the same chemistry, and is applicable to samples with COD between 40 and 400 mg O<sub>2</sub> l<sup>-1</sup>. Samples with higher COD values (>400 mg O<sub>2</sub> l<sup>-1</sup>) must be diluted while those with lower COD values (<40 mg O<sub>2</sub> l<sup>-1</sup>) may be determined by using more dilute dichromate and FAS solutions. Since small sample volumes are used, diluted dichromate (0.0167 mol l<sup>-1</sup>) and FAS (0.10 mol l<sup>-1</sup>) are prepared, and it is critical to obtain accurate volumes for samples and digestion solutions. Digestion vessels with premixed reagents and other accessories are commercially available. Otherwise, sample volumes and reagent quantities for various digestion vessels are suggested below. The digestion vessels are placed on a block heater preheated to 150°C for 2 h. The remaining K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> is determined by titrating with standard 0.10 mol l<sup>-1</sup> FAS. A blank containing the water reagents and DI is examined the same way for samples and the COD is calculated using eqn [3].

**Closed reflux: colorimetric method** The colorimetric method is another standard method to quantify COD values based on the change of chromate and dichromate concentrations. The chromate ion absorbs strongly in the 600 nm region while the dichromate ion has almost zero absorption. Therefore, samples with high COD (100–900 mg O<sub>2</sub> l<sup>-1</sup>) values convert sufficient amount of Cr<sup>6+</sup> to Cr<sup>3+</sup>, which can be determined in the 600 nm region. On the other hand, the dichromate ion absorbs strongly in the 420 nm region while the chromate ion absorbs weakly at this wavelength. Hence, samples with low COD

(<90 mg O<sub>2</sub> l<sup>-1</sup>) values can be determined by measuring the decrease of absorbance at 420 nm, which directly correlates with Cr<sup>6+</sup> concentration.

A calibration curve must be prepared before COD can be determined with this colorimetric method. At least 5 standards of KHP solution should be prepared to cover a range of sample COD values. Aliquots of standard KHP stock are diluted with DI water to the same volume for samples. A reference solution (blank) contains DI water only. The same reagent volumes, tube, and digestion procedure as for samples are followed (Table 1). Digestion vessels containing a blank, standards, and samples are placed on a block heater preheated to 150°C for 2 h. Samples are cooled to room temperature and their absorbances are measured against the blank. A linear calibration curve is created by measuring the difference between absorbencies of digested standards and the digested blank. COD values are determined based on calibration curves.

## Comparison of Chemical and Theoretical Oxygen Demand

Ideally, COD values obtained from the standard reflux methods should equal the solution's theoretical oxygen demand (ThOD), which is the amount of oxygen required to stoichiometrically oxidize compounds to end products, including CO<sub>2</sub>, NH<sub>3</sub>, and H<sub>2</sub>O. Examination of a database of 565 organic compounds has recently showed, however, that an average 85% of the ThOD value is obtained from COD tests due to the incomplete oxidation of some organic compounds by dichromate. Some halogenated aromatic and aliphatic hydrocarbons have especially low COD/ThOD ratios (as low as 0.03). The low COD/ThOD ratios also apply to many aliphatic alkane compounds with the lowest value down to 0.01. If a water or wastewater sample contains a large fraction of such refractory organic compounds, standard COD tests may be an inappropriate surrogate to

**Table 1** Suggested digestion vessels and sample and reagent volumes in COD tests

Digestion vessel	Sample volume (ml)	H <sub>2</sub> SO <sub>4</sub> volume (ml)	K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> volume (ml)	H <sub>9</sub> SO <sub>4</sub> (g)
500- or 250-ml Erlenmeyer flasks	50	75	25	1
16 × 100 mm capped tube	2.5	3.5	1.5	0.05
20 × 150 mm capped tube	5.0	7.0	3.0	0.1
25 × 150 mm capped tube	10.0	14	6.0	0.2

represent the degree of contamination. Alternatively, total organic carbon analyses may be performed to measure the total organic contents in the samples.

## Modifications of Standard Procedures

In addition to the incomplete oxidation of some chemicals with the reflux methods, laboratory wastes generated from the standard COD tests contain hexavalent chromium, mercury, and silver metals, all of which are classified as hazardous wastes by the US Environmental Protection Agency and their disposal is regulated under Resource Conservation and Recovery Act. Consequently, various modifications of the standard procedures or alternative methods have been reported for the COD test. These include: the replacement of hexavalent chromium, mercury, and silver metals; microwave digestion; automation and online COD measurement; and electrochemical oxidation to measure the sample COD.

### Elimination of Mercury and Chromate

Mercury is used in a standard COD test to suppress the chloride interference. Mercury sulfate can be used up for samples with chloride values as high as  $2000 \text{ mg l}^{-1}$ . For samples containing more than  $2000 \text{ mg l}^{-1}$ , however, various chloride removal methods may be considered. These include precipitation as silver chloride, ion exchange, addition of  $\text{Cr}^{3+}$  as a complexing agent, and oxidation of  $\text{Cl}^-$  to chlorine by pentavalent bismuth ( $\text{Bi}^{5+}$ ). Of these methods, the removal of chloride by  $\text{Bi}^{5+}$  proposed by Miller *et al.* is novel and promising. In this method, solid sodium bismuthate containing pentavalent bismuth oxidizes the chloride rapidly without affecting sample organics according to the following reaction:

A special chloride removal cartridge containing a glass-fiber filter (upper cartridge, for removal of particulates) and a column packed with a mixture of solid sodium bismuthate and an inert, free-flow agent (lower cartridge) is used. The acidified sample is drawn through the chloride removal cartridge under carefully controlled conditions of contact time, flow rate, and acid strength to allow chloride and bismuthate to react effectively without destroying sample organics. Solid sodium bismuthate is not soluble in the acidified solution and remains in the cartridge. The by-product, trivalent bismuth ( $\text{Bi}^{3+}$ ), dissolves in the acidified sample solution but has no effect on COD results. The glass-fiber filter containing particulates is removed from the top of the cartridge and combined with the treated liquid component in a COD reagent vial for

total COD measurement. Alternatively, soluble and particulate COD can be determined separately by digesting only the sample component of interest.

Permanganate ( $\text{Mn}^{7+}$ ) and trivalent manganese ( $\text{Mn}^{3+}$ ) have been proposed to replace hexavalent chromium as strong oxidants in COD analysis. In fact, the permanganate method is widely used in Japan to monitor organic pollution. Oxidation potentials of  $\text{Mn}^{3+}-\text{Mn}^{2+}$  and  $\text{Mn}^{7+}-\text{Mn}^{2+}$  half-reactions are 1.54 and 1.51  $E^\circ$  (V), respectively, both of which are greater than that of  $\text{Cr}^{6+}-\text{Cr}^{3+}$  half-reaction (1.35  $E^\circ$  (V)). Trivalent manganese ( $\text{Mn}^{3+}$ ) is a strong, non-carcinogenic chemical oxidant that changes quantitatively from purple to faint pink when it reacts with organic matter. Sample COD values are determined colorimetrically, and the color intensity is inversely proportional to the amount of COD in the sample. Unfortunately, the permanganate and trivalent manganese methods have relatively low oxidation power and poor reproducibility. Manganese ( $\text{Mn}^{3+}$ ) in sulfuric acid can oxidize  $\sim 80\%$  of synthetic and naturally occurring organic compounds.

### Microwave Digestion

The standard reflux methods require a long time (2 h) for the digestion step in the COD analysis. A rapid COD determination technique using microwave digestion has been developed. One of the advantages of using microwave digestion over the standard reflux method is that compounds such as pyridine and aromatic organic compounds are oxidized better. A special microwave with six individual magnetrons is designed to focus the microwave radiation on each sample in a 250 ml glass digestion tube. Each digestion tube is connected to a condenser circulating with cooling water to avoid any loss of volatile organic compounds in the sample.

An aliquot (20 ml) of a sample is added in the glass digestion tube, followed by the addition of 0.5 g of mercuric sulfate, 10 ml of dichromate solution, and 5 ml of sulfuric acid. The tube is placed into the microwave and connected to a condenser. An additional volume (25 ml) of sulfuric acid is added to the top of the condenser. The mixture is digested in the microwave at  $150^\circ\text{C}$  for 8 min. Excess dichromate in the digestion tube is determined with the standard titrimetric or colorimetric procedure. COD determination of real water and wastewater samples indicates that the results obtained from both microwave digestion and closed reflux digestion are consistent.

### Automation and Online COD Measurement

Standard reflux methods require 2 h of digestion, a length of time that would eliminate the benefits of

online COD measurement. With the development of microwave digestion and innovative thermal oxidation techniques, attempts to automate COD analysis in continuous flow systems (also called flow-injection analysis, FIA) have shortened the analysis period to 15 min.

One flow-injection method based on microwave digestion techniques is as follows. A sample is taken with an autosampler and mixed with reagents from a fast loop arrangement into a microwave heated chamber, where it is digested in an acid solution containing mercuric sulfate, dichromate solution, and sulfuric acid for 5–15 min. The process and system design ensures the constant sample volume and the reduced chromate ( $\text{Cr}^{3+}$ ) with green color is determined colorimetrically to give accurate COD values.

Other FIA methods have been developed by using innovative thermal oxidation techniques. The addition of a strong oxidizing agent, cerium(IV) sulfate, results in a high degree of sample oxidation. Potassium permanganate may also be used as both an oxidant and a colorimetric reagent during a segmented FIA to determine COD in aqueous environmental samples. But, it may not apply for analysis of samples containing abundant recalcitrant organic matter due to its limited oxidation power.

### COD Measurement with Electrochemical Oxidation

COD may also be determined with electrochemical methods. An electrochemical cell with the capacity for electrochemical oxidation of organic matter into water and carbon dioxide might enable a fast method to measure the sample COD based on coulometry (the number of electrons consumed in the degradation). The system includes a copper electrode, a potentiostat, and a personal computer. Copper in alkaline media can act as an electrocatalyst to oxidize organic matter. The potentiostat is used to maintain constant potentials during electrolysis. The data are recorded with a data acquisition system. The net charge, corresponding to the number of electrons consumed in the electrochemical oxidation, is correlated to the COD determined by standard reflux methods. The time required for a single sample COD measurement is ~30 min, which is much less than the 2–4 h required by the standard methods. However, electrochemical methods may not provide sufficient oxidation power to completely electrolyze all the organic matter. Furthermore, the electrodes may be easily contaminated with significant fouling, especially in a sample containing high concentrations of humic acid.

### Applications

COD is often used as a measurement of pollutants in water, wastewater, and aqueous hazardous wastes.

One application of the COD test is to measure soluble COD in wastewater, since characterization of total COD in wastewater is critical for accurate modeling of biotransformation in wastewater treatment processes.

Another application is to rapidly infer biodegradability of samples from the COD tests. This is commonly accomplished by establishing a correlation between COD and BOD. This method has been found successful when the proportions and types of materials in a wastewater remain relatively constant. For example, BOD in domestic wastewater samples from 5-day BOD tests can be approximated as  $\text{BOD}_5 = 0.476 \text{ COD}$ .

## Oil Pollution

**E Smith**, University of Plymouth, Plymouth, UK

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Oils are very complex mixtures of hydrocarbons in which the boiling points of components can vary from a few to several hundred degrees. Crude oils vary in their physical and chemical composition depending on their geochemical derivation, but all crude oils consist of a complex mixture of compounds comprised mainly of hydrocarbons. The hydrocarbon components of crude oil consist of straight and branched chain alkanes, cycloalkanes, and aromatics, and the relative content of these groups of compounds varies from oil to oil. Compounds containing oxygen, nitrogen, and sulfur, and various metals (Ni, V, Fe, Zn, Cu, U) are also present in crude oil.

The pollution of water and other matrices caused by the accidental leakage or chronic release of crude oil and refined products into the environment occurs each year. As the use and transportation of crude oil occurs on a large scale throughout the world, contamination of the environment with oil is an issue of concern. The amount of total hydrocarbons entering the oceans from all sources has been estimated at 2.35 million tons per year. Oil spills and hydrocarbons from land-based sources are usually limited to the coastal zone, but can be found even in the open oceans.

The characterization of a spilled oil in a contaminated environmental sample can be important for the assessment of environmental damage, and also in the selection of appropriate response and cleanup measures. The identification of an oil spill source is also extremely important for settling any dispute relating to liability and compensation. Petroleum hydrocarbon analysis may also be required to

determine the gradient of concentration around a point source, e.g., an oil platform, or provide baseline/benchmark and distribution concentrations.

Oil or petroleum products spilled on water undergo a series of biotic and abiotic processes that in combination are termed weathering, and cause changes in the physical and chemical properties of the oil. Weathering processes occur at very different rates but begin immediately after oil is released into the environment. These processes include evaporation, dissolution, dispersion, photochemical oxidation, water–oil emulsification, microbial degradation, and adsorption onto suspended particles. The changes in chemical composition of spilled oil can affect the toxicity of the oil and its biological impact over time, and also further complicate the identification of residual oil in the impacted environment. These factors make it difficult to select the most appropriate analytical methods for evaluating environmental samples.

A wide variety of instrumental and noninstrumental techniques are currently used in the analysis of oil hydrocarbons. These include gas chromatography (GC), gas chromatography coupled with mass spectrometry (GC–MS), infrared (IR) spectrometry, ultraviolet fluorescence spectroscopy (UVF) and gravimetry. Accurate and reliable analytical measurements are extremely important in order to unambiguously characterize spilled oil, to understand its fate and behavior, and to predict its long-term impact in environment. Despite advances in recent years in analytical technology, and in our understanding of the environmental fate of spilled oil, the complexity of oil means that there is no one method that can ‘do it all’ for the whole spectrum of oils and petroleum products that may be polluting an ecosystem. Each analytical technique measures only a subset of the complex mixture spilled or subsequently formed.

This article gives a brief survey of several analytical techniques currently used for the analysis

## Oil Pollution

### Introduction

Oils are very complex mixtures of hydrocarbons in which the boiling points of components can vary from a few to several hundred degrees. Crude oils vary in their physical and chemical composition depending on their geochemical derivation, but all crude oils consist of a complex mixture of compounds comprised mainly of hydrocarbons. The hydrocarbon components of crude oil consist of straight and branched chain alkanes, cycloalkanes, and aromatics, and the relative content of these groups of compounds varies from oil to oil. Compounds containing oxygen, nitrogen, and sulfur, and various metals (Ni, V, Fe, Zn, Cu, U) are also present in crude oil.

The pollution of water and other matrices caused by the accidental leakage or chronic release of crude oil and refined products into the environment occurs each year. As the use and transportation of crude oil occurs on a large scale throughout the world, contamination of the environment with oil is an issue of concern. The amount of total hydrocarbons entering the oceans from all sources has been estimated at 2.35 million tons per year. Oil spills and hydrocarbons from land-based sources are usually limited to the coastal zone, but can be found even in the open oceans.

The characterization of a spilled oil in a contaminated environmental sample can be important for the assessment of environmental damage, and also in the selection of appropriate response and cleanup measures. The identification of an oil spill source is also extremely important for settling any dispute relating to liability and compensation. Petroleum hydrocarbon analysis may also be required to

determine the gradient of concentration around a point source, e.g., an oil platform, or provide baseline/benchmark and distribution concentrations.

Oil or petroleum products spilled on water undergo a series of biotic and abiotic processes that in combination are termed weathering, and cause changes in the physical and chemical properties of the oil. Weathering processes occur at very different rates but begin immediately after oil is released into the environment. These processes include evaporation, dissolution, dispersion, photochemical oxidation, water–oil emulsification, microbial degradation, and adsorption onto suspended particles. The changes in chemical composition of spilled oil can affect the toxicity of the oil and its biological impact over time, and also further complicate the identification of residual oil in the impacted environment. These factors make it difficult to select the most appropriate analytical methods for evaluating environmental samples.

A wide variety of instrumental and noninstrumental techniques are currently used in the analysis of oil hydrocarbons. These include gas chromatography (GC), gas chromatography coupled with mass spectrometry (GC–MS), infrared (IR) spectrometry, ultraviolet fluorescence spectroscopy (UVF) and gravimetry. Accurate and reliable analytical measurements are extremely important in order to unambiguously characterize spilled oil, to understand its fate and behavior, and to predict its long-term impact in environment. Despite advances in recent years in analytical technology, and in our understanding of the environmental fate of spilled oil, the complexity of oil means that there is no one method that can ‘do it all’ for the whole spectrum of oils and petroleum products that may be polluting an ecosystem. Each analytical technique measures only a subset of the complex mixture spilled or subsequently formed.

This article gives a brief survey of several analytical techniques currently used for the analysis

of crude oil and petroleum products, and oil spill related environmental samples. The analytical method chosen will depend on the information required and a tiered approach can be used starting with a nonspecific method to identify samples that require more specific, lengthy, and expensive analysis. Methods may quantify total petroleum hydrocarbons (TPH) or specific individual components.

TPH methods generate a single number that represents the combined concentration of all petroleum hydrocarbons in a sample that are measurable by a particular method. The use of TPH concentrations to establish cleanup levels for soil or water is a common approach implemented by regulatory agencies. TPH is sometimes referred to as mineral oil, hydrocarbons, oil, extractable hydrocarbon, and oil and grease depending on the method used. There are many analytical techniques available that measure TPH concentrations in the environment. No single method measures the entire range of petroleum-derived hydrocarbons and because techniques can vary in the way hydrocarbons are extracted, cleaned up, and detected, they each measure a slightly different subset of the petroleum-derived hydrocarbons present in a sample.

Analytical measurements can be direct, i.e., the water samples are measured directly by the instrumentation, for example, UVF and immunoassay techniques can measure oil contamination directly in water samples. However, most methods measure the contaminated sample indirectly and therefore require sample treatment. The methods employed in sample treatment are common to all the indirect measurements.

## Sampling and Sample Treatment

### Collection and Preservation

Water samples are collected and stored in glass containers to avoid interference from plastics. For example, shallow water samplers utilizing 2.7l Winchester bottles have been used for more than 15 years up to depths of 50 m, although larger or smaller volumes (1–10 l) may be collected when the expected concentrations are very high or low. Samples should be stored in the dark and at low temperatures, in a fridge or freezer to minimize any loss of volatile components, and prevent photodegradation and microbial biodegradation of the sample. Also, samples should not be divided for analysis as this may introduce errors due to the adsorption of hydrocarbons onto the container walls. Adsorption of components to container walls can be minimized by carrying out the analysis rapidly, and it

has been recommended that water samples are extracted within 7 days of sampling, and analyzed within 40 days. If analysis is not carried out within 24 h the sample should be acidified to pH 2, or the solvent to be used for extraction be added at a ratio of 1:40. It is possible that shipboard contamination may occur when sampling water from leaks, spills, and lubricants during normal operations; it is therefore advisable to analyze fuel oil and bilge oil as part of a sampling strategy.

### Extraction

The extraction process separates the analytes of interest from the matrix, in this case the petroleum hydrocarbons from the aqueous phase. This is necessary for all nondirect methods of analysis.

The most commonly used method is extraction into a solvent using a separating funnel. The water sample is placed in a separating funnel, solvent added (e.g.,  $2 \times 50$  ml pentane) and the mixture shaken vigorously. The first aliquot of solvent may be used to rinse the sampling container to take into account any hydrocarbons adhered to the container walls. After layer separation the solvent layer (extract) is dried with desiccant (anhydrous sodium sulfate). Multiple extractions will increase recovery and the extract may then be concentrated prior to analysis.

Methylene chloride has been the solvent of choice for many semivolatile analyses due to its high extraction efficiency, low cost, and specification by many regulatory methods. In the past chlorofluorocarbon solvents, such as trichlorofluoroethane, have been used for oil and grease analyses, because of their low human toxicity, and spectral qualities (i.e., no absorption at  $2930\text{ cm}^{-1}$ , the wavelength generally used for sample measurement). However, owing to the detrimental effects of chlorofluorocarbons on stratospheric ozone, their use is being phased out.

Other methods in common use include purge and trap and headspace analysis for volatile components, and continuous liquid–liquid extraction and solid-phase extraction (SPE) for semivolatile compounds. Volatile compounds in water may be extracted by purging with an inert gas and trapping the compounds on a sorbent. These may then be analyzed by heating the sorbent to release the volatile compounds into a gas chromatograph. In headspace analysis the water sample is placed in a closed vessel with a headspace, and heated to drive the volatiles into the gas phase. Samples containing heavy oils or high hydrocarbon concentrations may contaminate purge and trap instrumentation, whilst this is minimized in headspace analysis as only the volatile components enter the instrument. In continuous liquid–liquid

extraction, rather than shaking solvent with the water sample, the solvent is continuously heated and sprayed on top of the water. This method is more time consuming than using a separating funnel but useful when samples contain emulsion forming solids. SPE involves passing the water sample through a cartridge or disk containing adsorbent such as silica or alumina. After extraction the analytes are eluted with solvent.

### Concentration

Concentration of the sample extract increases the capability to detect the compounds of interest. It is commonplace that analytes are present at low concentrations even once extracted. Concentrating the sample extract lowers the detection limits, and this may be performed for volatiles by sorbent trapping or cryogenic trapping, and for semivolatiles by methods such as rotary evaporation, a Kuderna Danish concentrator, and/or nitrogen evaporation. Care must be taken not to reduce the samples to dryness when removing the extracting solvent; otherwise losses of the lower molecular weight components (e.g., naphthalene) may occur.

### Cleanup

The aim of the cleanup step is to remove interfering compounds prior to analysis. This step may also be used to isolate a particular fraction containing analytes of interest. Cleanup is usually based on passing the extract through a glass column containing a sorbent such as silica, and eluting the petroleum hydrocarbons with solvent whilst leaving interfering compounds on the column. This is an important element in gravimetric and IR-based analyses as they are very susceptible to nonpetroleum hydrocarbon interferences; for example, polar compounds such as animal and plant fats may be inappropriately identified as petroleum constituents. Prior to analysis by GC the sample can also be fractionated during cleanup into aliphatic and aromatic components, which can be analyzed separately.

## Measurement and Identification

### Gravimetry

Gravimetric methods may be used to quantify TPHs from water samples. The water is extracted with a solvent (e.g., carbon tetrachloride), the solvent extract is passed through a florisil column to remove biogenic interferences, and the eluate is evaporated, dried at 105°C, and weighed. The advantage of this method is that it is simple, fast, and inexpensive. The range of application is typically up to

1000 mg kg<sup>-1</sup> with detection limits of 5–10 mg l<sup>-1</sup> in water. However, this method is not suitable for low molecular weight compounds and provides no detailed information on the nature of the oil.

### Infrared Spectrometry

IR spectroscopy can be used to measure the total hydrocarbon content from a sample. The hydrocarbons are extracted from acidified water using a nonhydrocarbon solvent, e.g., carbon tetrachloride and the absorption measured. IR is normally used to measure the saturated hydrocarbon content of a solution and not the aromatic hydrocarbon content. For example, the absorbance of the extracted material is measured at 2930 cm<sup>-1</sup> corresponding to the C–H stretching frequency of CH<sub>2</sub> groups, although some methods use multiple frequencies including 2960 cm<sup>-1</sup> for C–H stretching in CH<sub>3</sub> groups and 3030 cm<sup>-1</sup> for C–H stretching in aromatic rings. Quantification is based on the response of solutions of oil but problems may be encountered with the preparation of standards and samples. The extracting solvent must not contribute to the response; hence, carbon tetrachloride is commonly used, and biogenic interferences are removed by passing the extract through a florisil or silica column. This method may be used for the analysis of natural and saline waters, sewage and effluents with a limit of detection of 1 mg l<sup>-1</sup> in water.

### Immunoassay

Immunoassay methods have been developed to correlate TPH with the response of antibodies to specific petroleum components. A number of different testing kits based on immunoassay technology are available for rapid determination of TPH. These kits are self-contained portable systems designed to conduct analysis in the field, including sample preparation and instrumentation to read the assay results. Water samples are added directly so there is no lengthy sample preparation. A known amount of labeled analyte is added after the sample, typically an enzyme with an affinity for the antibody, and the sample analyte competes with enzyme labeled analyte on the antibodies. A color development reagent reacts with the enzyme and the absorbance is measured, which is inversely proportional to the concentration. Test kits are available for TPH, BTEX (benzenes, toluenes, ethylbenzenes, and xylenes – low molecular weight volatile compounds), and polycyclic aromatic hydrocarbon (PAH) analysis, but as their precision and accuracy are lower than standard laboratory methods immunoassays are only useful as a screening technique. Typical detection

limits for TPH range from 10 to 500 mg kg<sup>-1</sup> in soil and 200–500 µg l<sup>-1</sup> in water.

### Ultraviolet Fluorescence

The determination of petroleum hydrocarbons in seawater by fluorescence is a well-established technique and has been used in routine analysis in many parts of the world. It can be used to monitor very low concentrations of oil in seawater owing to its greater sensitivity than absorption techniques and has also shown good results for waters in the vicinity of oil spills. The simplicity, speed, and low limit of detection of this technique, coupled with its low cost when compared to other techniques, make it suitable for large-scale monitoring. Several intercalibration exercises have shown good performance and reproducibility of the UVF method, and it has been adopted for many national and international monitoring programs. The main disadvantage of this technique is that due to the complex and varying composition of hydrocarbons in oil and seawater it is not possible to determine actual concentrations as it is not known what is being measured. However, its strength lies as a screening tool that may justify spending resources for further in-depth analysis.

As there is no absolute measure of fluorescence emission, the spectrophotometer is first calibrated with solutions of a reference oil standard. The hydrocarbon concentration is determined by measurement of the fluorescence emitted at 360 nm whilst the sample is excited at 310 nm. This is compared with the fluorescence of standard solutions of oil (e.g., Ecofisk crude oil) under the same conditions. For diesel oil standards the fixed wavelengths used are excitation at 270 nm and emission at 330 nm. The method relies on fluorescence of the more water-soluble aromatic components of the oil; whilst sensitive it is very dependent on oil composition and suitable calibrants. Synchronous excitation-emission spectra (230–500 nm) are run for blanks, standards, and samples and comparison of the spectra indicate whether or not the standard contains aromatic hydrocarbons in a similar boiling point range to the samples, i.e., whether an appropriate standard was used. It is often impractical to make up standards for complex petroleum hydrocarbon samples; consequently, UVF may be measured in equivalents of a specific compound such as chrysene, which has been recommended by the World Health Organization. This technique also enables oil to be measured directly in water thus avoiding the need to extract the water sample with organic solvent. All measurements are carried out within the linear range of the instrument to avoid the effects of quenching, which

in practical terms is taken to be 0–10 mg l<sup>-1</sup> with the limit of detection at ~0.24 µg l<sup>-1</sup>. If the purpose of the analysis is to look at extent of oil pollution, the presence of combustion or naturally derived PAH would represent an interference. The use of synchronous excitation emission spectroscopy can sometimes highlight such interferences but more detail is gained by GC analysis. Representative synchronous excitation–emission spectra for jet fuel, diesel oil, paraffin, and Forties crude oil are shown in Figure 1.

### Gas Chromatography and Gas Chromatography–Mass Spectrometry

A major shortcoming of the nonspecific methods is that the information provided from using such methods does not afford details of the individual components present and thus petroleum source specific information. If oil pollution is found at a site, one of the first questions will be what is it, followed by where did it come from. GC, in addition to providing quantitative measurements, can provide details of the components present at a contaminated site and thus indicate where the pollution has come from.

Most GC-based methods are applied to sample previously separated into aliphatic and aromatic fractions using liquid chromatography or conventional column chromatography. The two fractions are then analysed on a gas chromatograph with a flame ionization detector (GC-FID). The TPHs are usually estimated by integrating the areas of the resolved and unresolved components of both fractions. For GC-based methods TPH is defined by anything extractable by a solvent or purge gas and detectable by GC-FID within a selected carbon range. Cryogenic cooling can also be employed to analyze the low molecular weight compounds. Detection limits for GC-FID TPH can be as low as 50 µg l<sup>-1</sup> whilst individual analytes may be detected at approximately one order of magnitude lower.

Oil and oil products can be readily identified from their GC traces during the early stages of an oil spill especially where the spilled oil is heavy and background hydrocarbon levels are low. A simple technique is to produce a chromatogram under standard conditions (column packing, flow rate, temperature), which can be compared to the trace of a sample of material suspected to have been discharged. If the type of contaminant is unknown a 'fingerprint' analysis can help in identification by comparison of chromatograms to reference materials. Certain fuels can be identified by characteristic reproducible chromatographic patterns. Hydrocarbon fuels give chromatograms with regularly spaced peaks (consecutive members of homologous series of compounds) whilst

**Figure 1** Synchronous excitation/emission fluorescence spectra. (Reproduced with permission from Kelly CA, Law RJ, and Emerson HS (2000) Methods for the analysis of hydrocarbons and polycyclic aromatic hydrocarbons (PAH) in marine samples. *Aquatic Environmental Protection Analytical Methods*, CEFAS Lowestoft 12, 18pp. © British Crown.)

lubricating oils have fewer resolved peaks. Correspondence of retention times and the overall envelope shape of the chromatogram may be sufficient to characterize the contamination. Total ion chromatograms for jet fuel, diesel fuel, paraffin, and Forties crude oil are shown in **Figure 2**. Complications can occur in interpretation if the pollution is not sampled immediately after discharge due to the loss of volatile components and degradation of the oil.

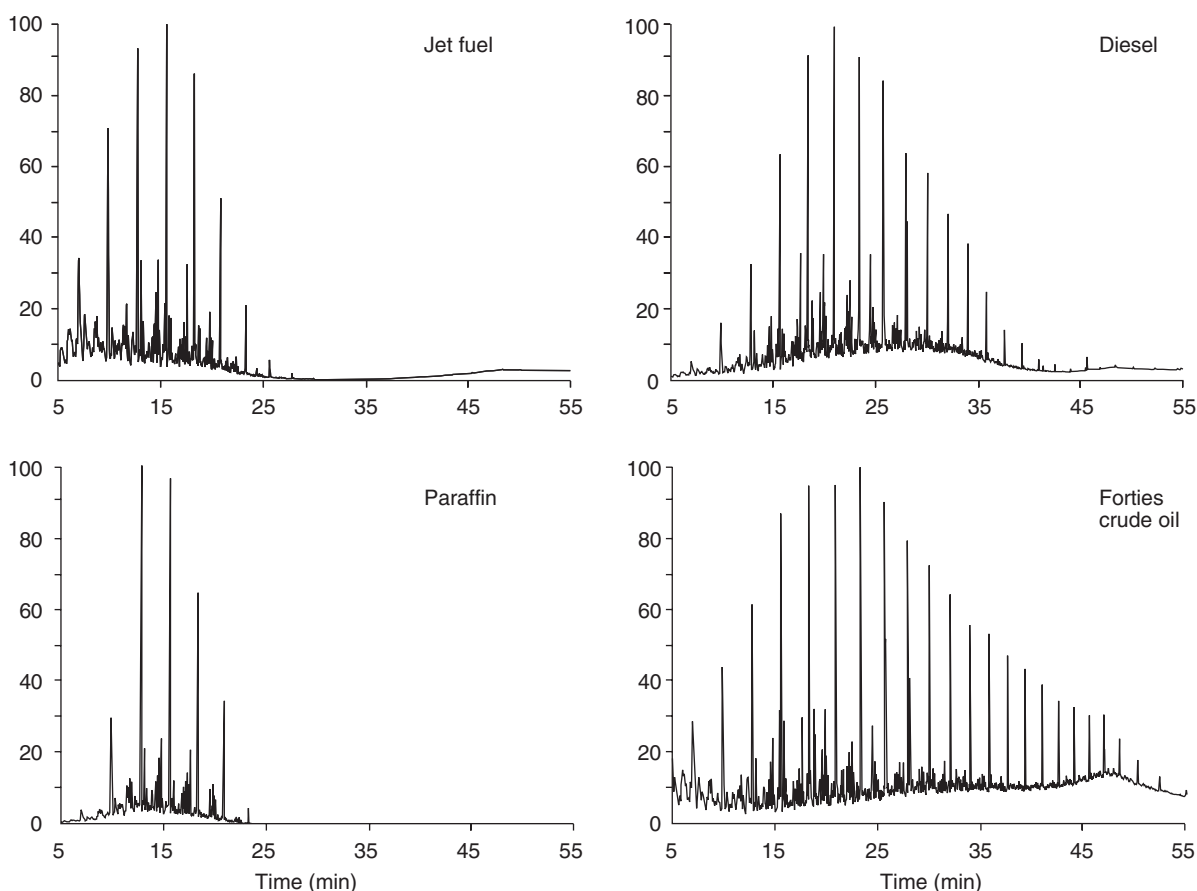

The combination of chemical separation by GC coupled with the spectral resolution afforded by MS permits the identification of specific compounds. The selection of appropriate analytes is dependent mainly on the type of oil spilled and the particular environmental compartment being assessed. The aliphatic fraction contains the majority of the compounds in petroleum, i.e., n-alkanes, branched alkanes, isoprenoids, cycloalkanes including steranes and triterpanes, as well as an unresolved complex mixture of saturated hydrocarbons. The aromatic fraction generally contains more toxic and more persistent compounds than the aliphatic fraction including PAHs. Specific compound determination is especially important for individual PAHs and biomarker compounds at the parts per billion concentration. To further enhance detection of target compounds the mass spectrometer may be run in selected ion monitoring mode, which increases the limit of detection by approximately one order of magnitude over that of full scan operation.

A variety of diagnostic ratios, especially for PAH and biomarker compounds, for interpretation of chemical data from oil spill have been proposed for oil source identification and monitoring of weathering and biodegradation processes. Weathering processes in the environment cause changes in the physical and chemical characteristics of the spilled oil. Significant losses occur due to evaporation of the low molecular weight alkanes but the  $nC_{17}$ /pristane and  $nC_{18}$ /phytane ratios remain virtually unaltered from the original oil and so can be used to determine the source of the oil. However, if the oil is heavily weathered or biodegraded these traditional diagnostic ratios become less reliable, but can be used to indicate microbial degradation at a site. The ratio of phenanthrenes to dibenzothiophenes has been used to discriminate and identify different refined oils, whilst priority pollutant PAH and their alkylated homologs may be used to differentiate between petrogenic and combustion (pyrogenic) sources. The contribution by biogenic hydrocarbons can also be determined.

## Standard Methods

There are many standard methods available for the analysis of oil pollution in water by regulatory agencies. The main techniques used have been summarized within this article, whilst further details

### Introduction

The principles of the microbiological analysis of water have evolved over nearly a century and are important tools for the protection of public health all over the world. This article will focus on the principles and applications of detection and enumeration methods for health-related microorganisms, as they are used for the sanitary control of drinking water, and fresh and marine waters used for recreation and the growing of shellfish. It will not deal with methods for ecological research, which may be very specific, although the general outline described here may well be applicable. Likewise, methods for the examination of sludges and sediments will not be discussed. They will usually require specific sample pretreatment methods; the final stages of the analysis may again be very similar to those described here.

The microbiological analysis of water aims at a great variety of microorganisms, including viruses, bacteria, and protozoa. The target organisms may be pathogenic to man or they may be harmless model organisms. The different purposes of the sanitary microbiological analysis of water are described in the section on applications.

Microbiological analyses are extremely sensitive: just a single infectious particle may be detected in volumes of up to 1000 l of water. The weight of a bacterium is in the order of  $10^{-12}$  g; the weight of a virus may be as low as  $10^{-17}$  g. Hence, the limit of detection is between  $10^{-15}$  and  $10^{-20}$  g l<sup>-1</sup>. Many microbiological test systems are based on amplification of single particles to such concentrations or size that they can be detected by the naked eye. Consequently, the precision of these tests is governed by the behavior of individual particles in the object to be sampled. This requires statistical models for data analysis that differ from the normal distribution. Ideally, the Poisson distribution can describe microbial counts, but in many practical cases the distribution of microorganisms in the sample shows a greater degree of dispersion. Different proposals for adequate statistical models have been made, such as the 'extra-Poisson' model, the negative binomial distribution, or the lognormal distribution. This last model is often used because it can easily be adapted

to standard statistical methods by simple log-transformation of the data, and because interpretation of the final results is relatively straightforward. Using this approach, the standard principles for describing precision of analytical methods in terms of repeatability and reproducibility can also be used for microbiological analysis.

It must be realized that owing to the detection of single particles, there is a lower limit to precision that cannot be improved. In fact, if better repeatability is reported, this is suspect. The trueness of microbiological methods can only be expressed in relative terms, because there is no 'absolute' method for determining the number of microorganisms of a particular type in a sample. Nevertheless, the concept of accuracy can be used to describe the performance of methods relative to each other. Important aspects of accuracy are the recovery, the interference by competitive microorganisms, and the ability to differentiate the target organisms from other organisms.

### Sampling

#### Sampling Apparatus

Most microbiological samples are collected in borosilicate glass bottles that are sterilized before use by heat treatment (autoclaving for 15 min at 121°C or hot air for 1 h at 170–175°C). Polypropylene bottles that withstand repeated sterilization can also be used. Commercially available, presterilized sample containers are available and may also be suitable. Sample containers can be supplemented with preservative agents before or after sterilization, depending on the type of water to be sampled and the heat stability of the agents. For most practical purposes in health-related water microbiology, sample containers need not be pretreated to prevent adsorption of the target organisms to the wall of the container (this may be quite different in ecological research). However, free-living amoebas adsorb strongly to glass surfaces and pretreatment with silicon compounds is necessary.

Sample volumes greater than 1 l are usually collected by pumps. It is imperative that these pumps can easily be cleaned and disinfected. Pumping equipment can be disinfected by heat treatment or by using a sodium hypochlorite solution (75 mg l<sup>-1</sup> free available chlorine at a contact time of 5 min is usually sufficient), allowing repeated use in the field.

## Sampling Methods

Grab sampling is the most commonly employed method for sample volumes up to 10 l, the actual technique depending strongly on the water body to be sampled (e.g., sampling from taps for drinking water in mains, or bottles with attached weight for sampling surface water at a specific depth). Proper aseptic techniques should be used to prevent contamination of the sample. When sampling drinking water in open reservoirs, great care should also be taken to ensure that the sampling process does not contaminate the water under study. Larger sample volumes, which are usually necessary for the analysis of viruses and protozoa, may take several hours to collect and are therefore usually taken by continuous pumping. If standard bacteriological analyses are made in parallel, the use of the standard grab sampling technique is only appropriate if the temporal variations at the sampling station are known to be small. In all other cases, a continuous sampling method must also be used for these determinants, for example, by filling a 1–5 l bottle with a tube pump and subsampling in the laboratory after careful homogenization.

## Sampling Plan

Microbial counts may vary significantly in time and in place, and this aspect is often not correctly accounted for in sampling plans. It has been shown that effects of between-sample variation may influence the outcome of studies on the relationship between water quality and health and that significant correlations can only be obtained with samples from well-defined sampling points. In general, repeated samples of relatively small volumes should be collected and eventually pooled in the laboratory, rather than collecting a few large-volume samples and repeatedly subsampling in the laboratory. Expert statistical assistance should be sought when designing sampling plans.

## Sample Treatment and Storage

### Samples for Bacteriological Examination

The bacterial content of a water sample is highly unstable and cannot be preserved for long periods by simple methods. Ideally, the analysis should begin within a few hours after sampling and, during this period, the sample should be protected from light and temperature changes by placing it in an insulating container. If samples cannot be examined directly, they should be cooled rapidly by placing them on melting ice or in a high-capacity refrigerator. Ideally, the temperature of the sample should drop below 4°C within 4 h, but the sample should not freeze. Under these conditions, most determinants will not change

significantly in a period up to 24 h, whereas, for example, counts of spores of *Clostridium perfringens* may be stable for periods up to a week. Because local conditions may vary, it is recommended that studies of the effect of sample storage on bacteriological determinants be carried out at least on a national level and preferably by individual or central laboratories. In many cases, transport of samples on melting ice or examination within 24 h is only possible at high cost or is not possible at all. Many solutions to this problem are used, such as simple transport at ambient temperatures, addition of preservatives (e.g., boric acid), prefiltration, and shipment of filters on transport media. Any procedure will most probably result in changes in the test result and they should be assessed and reported. The acceptability of erratic test results should be weighed against the financial or logistic gains, and possible changes should be taken into account when interpreting the data.

Two types of water constituents may have a strong effect on the bacterial counts of water samples and should be neutralized during the sampling process. These are disinfectant residuals and heavy metals in concentrations exceeding  $10 \mu\text{g l}^{-1}$  (notably copper). Disinfectant residuals are conventionally neutralized by sodium thiosulfate to a final concentration of  $30 \text{ mg l}^{-1}$  (this is sufficient to neutralize chlorine residuals up to  $5 \text{ mg l}^{-1}$ ). Heavy metals are 'neutralized' by adding chelating agents such as ethylenediaminetetraacetic acid (EDTA) or nitrilotriacetic acid (NTA) to a final concentration of  $50 \text{ mg l}^{-1}$ . NTA is recently gaining preference because it is easily biodegradable. Neutralizing agents should be added to the sample bottle before filling, so that instantaneous action is guaranteed. In order to prevent recontamination, it is advisable to add a solution of these agents to the sample containers before sterilization. Sodium thiosulfate withstands both autoclaving and dry sterilization, whereas EDTA and NTA will only withstand autoclaving. It is also possible to combine sodium thiosulfate and EDTA or NTA in the wet sterilization process if the pH is above 9.

### Samples for Virological Analysis

Virological analysis usually involves processing of volumes between 10 and 1000 l. It is possible to collect sample volumes up to 10 l in sterile containers and to transport them to the laboratory. These samples should be treated as bacteriological samples (but no neutralization of heavy metals is usually necessary). Again, a procedure that does not permit rapid cooling and limited time of transport before analysis should be validated before use. For larger volumes, it is advisable to perform a first sample processing step

in the field. This usually involves adsorption of the viruses in the water to some type of filter, such as ultrafilters, negatively or positively charged membranes, or glass wool. Depending on the nature of the filter material and the water quality (pH, ionic strength, humic acids, etc.), it may be necessary to promote adsorption by decreasing the pH, using in-line injection of hydrochloric acid or addition of cations such as  $Mg^{2+}$  or  $Al^{3+}$ , or both. If the water has been disinfected, it may also be necessary to neutralize any residuals by injection of sodium thiosulfate. After adsorption, the viruses are usually eluted from the filter by a highly proteinaceous solution at a defined high pH (e.g., beef extract). This elution step is preferably performed in the field or it should be done in the laboratory as soon as possible. Primary eluates can be further treated directly or can be stored for long periods at  $-70^{\circ}C$  or below. Because many variables affect the recovery of the virus concentration procedure, it is advisable to evaluate the recovery of a particular method before use. This can be done by seeding simulated samples with stock virus suspensions or with waters with a high degree of natural pollution, such as sewage. Ideally, recovery studies should be carried out for every type of field sample, but this may add considerably to the cost of virological analysis. A suitable alternative is to evaluate the recovery of the concentration procedure for bacteriophages and to assume that constant performance for bacterial viruses also indicates constant performance for human viruses.

### Samples for Protozoological Analysis

Two types of protozoa are of interest in health-related water microbiology. Although not taxonomically correct, they are usually described by reference to characteristics of their life cycle as the 'free-living amoebas' and the 'parasitic protozoa'. Free-living amoebas are able to complete their entire life cycle in the inanimate environment. Whereas most species are harmless to man, some may be pathogenic. *Naegleria fowleri* is the causative agent of a lethal form of meningoencephalitis, while certain species (e.g., *Hartmanella* spp.) are of interest because they live in symbiosis with the pathogenic bacterium *Legionella pneumophila*. Parasitic protozoa can only complete their life cycle in a suitable animal host and they are excreted in the feces as highly resistant (oo)cysts. The two most important species for water hygiene are *Giardia lamblia* and *Cryptosporidium parvum*.

**Free-living amoebas** Because these organisms are actively multiplying in the environment, there is usually no need to examine very large volumes of sample: 1–3 l are commonly examined. The amoebas are filtered

from the sample by conventional membrane filtration (pore size 1–3  $\mu m$ ) with a low vacuum to prevent passage of the flexible amoebic cell through the pores.

**Parasitic protozoa** As for viruses, grab samples for parasitic protozoa can be transported to the laboratory, but when volumes up to 100–1000 l need to be examined the sample is filtered directly in the field. Protozoan (oo)cysts are retained in microporous (1  $\mu m$ ) filters on the basis of size; hence, it is not necessary to add acids or cations. Because of the high resistance against disinfectants, it is normally not necessary to neutralize any residuals, but this is however done when, e.g., swimming pools are sampled. In samples of this kind, the relatively high chlorine residual concentrations can interfere with staining of the (oo)cysts wall with fluorescent-labeled monoclonal antibodies and thus hamper microscopic detection. The sampling apparatus must be clean and free from protozoan (oo)cysts but need not be sterile. High chlorine concentrations to clean the apparatus should be avoided and the apparatus should be thoroughly rinsed before sampling.

Recovery of (oo)cysts from filters is normally done in the laboratory and filters are transported at 2–5 $^{\circ}C$  in the dark. A maximum period of 48 h between sampling and sample processing is generally considered acceptable. Retained particulates are eluted from the filter with a detergent solution and are further concentrated by centrifugation. *Giardia* cysts and *Cryptosporidium* oocysts are separated from other particulate debris in the concentrate by an immunomagnetic separation (IMS) technique. Magnetic latex beads coated with antibodies directed toward the (oo)cyst walls are gently mixed with the water concentrate allowing beads–(oo)cyst complexes to form. These complexes are recovered from the water concentrate by using a magnet, thus separating the (oo)cysts from other debris. Finally, the (oo)cysts are retrieved from the beads for microscopic detection. Other methods of sample purification, like flotation or flow cytometry, are also being used, but IMS is presently the most commonly applied method around the world. The recovery of this filtration–concentration method depends on many factors and requires experienced analysts. It is therefore important to validate all steps of the procedure before applying it to actual samples. This can be done by seeding water samples with known numbers of (oo)cysts from stock suspensions.

### Techniques

A great variety of detection methods for microorganisms in water is available. These are briefly described below.

## Bacteria

**Culture methods** Culture methods for bacteria can roughly be divided into two categories: liquid enrichment methods and plate count methods. In liquid enrichment methods, a test portion is inoculated into a growth medium that has been formulated to stimulate growth of the target organisms and to suppress growth of all other organisms ('background flora'). Choosing an appropriate incubation temperature and time enhances the selective nature of the growth medium. If the target organism is present in the test portion, this will result in a positive signal, irrespective of the original number. In their simplest form, liquid enrichment methods therefore give presence/absence type of information. In order to obtain semiquantitative information, it is usual to examine a series of different volumes (e.g., 100, 10, 1, and 0.1 ml) to produce an endpoint type of result. If a series of different volumes is examined in replicate, e.g., three- or fivefold, it is possible to use a statistical method known as the 'most probable number' (MPN) technique to estimate the original concentration of the target organism. The precision of this estimate is low (e.g., the 95% confidence interval of a fivefold MPN estimate is roughly between one-third and three times the analytical result). To improve precision it is sometimes recommended performing 96-well MPN estimates in microtiter trays, but with this technique only a limited volume of sample can be examined.

For more precise results the plate count method is more appropriate. The precision of this method is basically determined by the distribution of the target organisms in the sample (see above). In the plate count method, a test portion is inoculated onto the surface of a growth medium that has been solidified by addition of agar (spread-plate method). Each individual cell of the target organism will multiply into a colony that is visible to the naked eye. If several cells of the target organism are physically 'connected' (e.g., by adsorption to a particle of suspended matter), this will also result in one colony. The results of the plate count technique are therefore expressed as 'colony-forming particles' (cfp). Each cfp represents one or more cells of the target organism in the original sample. The pour-plate method, in which the test portion is mixed with the liquefied agar medium, poured into Petri dishes, and incubated after solidification, and the membrane filtration method, in which the test portion is filtered through a membrane filter (usually of 0.45  $\mu\text{m}$  pore size) that is placed on the growth medium, are variations.

It is generally not sufficient simply to inoculate a test portion in or on a selective growth medium to

obtain accurate results. Often, cells of target organisms will be damaged to some degree by physical or chemical stress and it may be necessary to revive them before placing them in the selective environment of the growth medium. This resuscitation procedure is an integral part of many culture methods and usually involves incubation in a less selective medium and/or at a less restrictive temperature. The selective growth medium is usually supplemented with some kind of specific detection system to differentiate growth of target organisms from that of background organisms. The detection system can be based on fermentation of specific sugars, enzymatic degradation of specific substrates, motility, reduction of hydrogen acceptors, etc., and will usually result in recognizable color changes, gas production, and so on. Routine methods should preferably be designed to produce results with an acceptable degree of selectivity at this point. For more critical examinations (e.g., detection of specific pathogens), it may be necessary to examine further the 'presumed' positive results by one or a series of confirmatory tests or even to proceed to identification at the genus, species, or type level. The objectives of the analysis determine the necessary level of confirmation and identification.

**Microscopic methods** Direct enumeration of bacteria in water by microscopic methods has only limited applications in health-related water microbiology because the detection limit is relatively high and because the microscopic image provides only a marginal clue to the identity of the bacteria. This latter fact can theoretically be overcome by specific immunofluorescence methods, but only few selective antibody preparations are readily available. Furthermore, microscopic methods do not commonly differentiate between living and dead cells, which makes interpretation of analytical results in terms of health risks impossible. Several methods have been developed to assess the viability of single cells by microscopic methods, such as exclusion of certain dyes (indicating integrity of the cell wall), reduction of tetrazolium salts (indicating active respiratory metabolism), and cell elongation in the presence of nalidixic acid (indicating active biosynthesis). These methods are time consuming and require the expertise of a research laboratory. It has been demonstrated that in a bacterial population under stress the detectability by culture methods is lost more readily than the viability using microscopic methods and claims have been made that bacteria in this 'viable, nonculturable stage' are infectious to man and experimental animals. However, these claims have not been supported to a great extent by well-published material and solid contradictory evidence has been

published. The infectivity of viable, nonculturable bacteria presently remains the subject of considerable debate.

**Molecular methods** Molecular methods have been explored in many research laboratories in recent years and their use has increased tremendously. Molecular methods include hybridization, restriction enzyme analysis, amplification, cloning, and sequencing. Hybridization and restriction, alone or in combination, are suitable techniques for identification of isolates that are obtained in pure culture. Fluorescence *in situ* hybridization involves direct detection of organisms after concentration on membrane filters with species-specific oligonucleotide probes labeled with fluorescent dyes, without the need for preculture. Amplification and cloning (i.e., amplification in a biological vector) produce nucleic acid fragments that can be compared to nucleotide sequences in databases (e.g., available on the Internet), which provide information on (sub)types, genetic relations, origin, etc., of the target organism. The most widely used amplification method is the polymerase chain reaction (PCR), in which single (c)DNA fragments are serially amplified by *in vitro* enzyme reactions. PCR can be used for direct detection of microorganisms in water samples, but can also be applied to identify isolates. Although PCR is a sensitive method, concentration of water samples is required. It enables detection of nonculturable organisms, but it cannot distinguish between live and dead organisms and may also detect dead organisms or past contamination because DNA is very stable in the environment. mRNA molecules, on the contrary, are very labile and have a rapid turnover. With reverse transcriptase-PCR (RT-PCR) mRNA can be amplified and the presence of this RNA indicates the presence of living or recently dead cells in a sample. Differentiation between live and dead cells can also be accomplished by preceding the PCR by a short enrichment step allowing culturable bacteria to multiply. PCR is basically a presence/absence technique but it can be used in an MPN-type assay to produce semiquantitative results. In recent years development of real-time quantitative PCR systems that are very promising for direct molecular detection and quantification of microorganisms in water samples have made progress towards quantification of PCR.

## Viruses

**Culture methods** Culture methods are most widely employed to detect viruses in concentrates from water samples. Bacterial viruses (bacteriophages) are

increasingly being used as an easily detectable surrogate for human viruses. The most frequently used (continuous) cell lines for supporting the multiplication of human viruses are derived from humans (tumor cells) or from primates (such as monkey kidney cells). The actual virus assay can be performed by a great variety of methods including the plaque assay, which is a quantitative method, or assays with cell cultures in liquid medium, which are presence/absence methods.

Detection of virus multiplication is usually done by observation of the host cell under the microscope for changes in structure or size (cytopathic effect). There are more than 100 types of human viruses that can be present in a water sample and for only a few types a cell-culture method is available that will result in readily observable cytopathic effects. Other viruses will be able to undergo only a limited degree of replication in cell culture and the products of this multiplication (proteins and/or nucleic acids) can be detected in the cell cultures by immunological or molecular methods. These techniques have expanded the range of detectable viruses and they have improved the sensitivity of the assay but, nevertheless, no cell-culture method is presently available for many important waterborne viruses.

**Immunological methods** Methods such as the enzyme-linked immunoassays and radio immunoassays have wide application in the clinical field but are not suitable for water analysis because of their high detection limit.

**Molecular methods** Direct detection of viral DNA or RNA is limited in use because of the high detection limit and amplification by the PCR assay is necessary to produce a detectable signal. Any virus with a known genome sequence may be detected by molecular methods since a set of probes or primers can be selected. Methods for cleaning up environmental concentrates are necessary for the removal of inhibitors of the amplification reaction. PCR has been successfully used to detect viruses at levels similar to or even lower than those detected by culture methods. Some important waterborne viruses cannot be cultured and their detection by molecular methods does not discriminate between infectious and noninfectious particles. In case viruses can be cultured the sensitivity of the assay may be improved by molecular detection of virus offspring. Quantification of virus DNA and RNA containing particles is rapidly improving with the development of real-time PCR assays but so far has only been available for part of the relevant waterborne pathogenic viruses.

## Protozoa

**Culture methods** Free-living amoebas are readily culturable on a lawn of living or killed bacteria that are used as a food source. The amoebas can be washed from filters used for concentration, after which drops of concentrate are placed on the assay medium to produce a semiquantitative result. It is also possible to place the filter directly (facedown) on the assay medium and to observe the margins of the filter for the emergence of amoebas, which will occur in due time. By using elevated incubation temperatures (37–44°C), it is possible to preliminarily differentiate between pathogenic and nonpathogenic *Naegleria* species, but complete identification and virulence testing require specialized laboratory facilities (e.g., inoculation in cell cultures or in mice).

*In vitro* cell culture assays have been developed for demonstration of *Cryptosporidium* oocyst infectivity. A variety of cell lines is in use (e.g., Caco-2, HCT-8, MBDK) and most of the life cycle of *Cryptosporidium* can be completed *in vitro*. The assays have been successfully applied to environmental samples, but detection of infectivity of environmental oocysts is hampered by lack of sensitivity of the assays in some situations. Cell culture assays can however satisfactorily be used in disinfection studies.

**Microscopic methods** The detection of (oo)cysts of the parasitic protozoa *Giardia* and *Cryptosporidium* is usually done by immunofluorescence microscopy. Various preparations of mono- or polyclonal antibodies are available but none of them is fully specific for the human pathogenic species. Confirmation of the microscopic image involves measuring the size and studying the shape of the fluorescent objects, and examination of internal structures using phase-contrast microscopy or interference-contrast microscopy. It is unusual for an (oo)cyst from an environmental sample to reveal all ideal attributes, so that a certain degree of subjective interpretation is presently unavoidable. Microscopic assays that differentiate between living and dead (oo)cysts are based on inclusion or exclusion, or active uptake of certain fluorescent dyes.

**Molecular methods** These methods and their applications are still under development, but much progress has been made in recent years. Many PCR-based methods for detection of *Cryptosporidium* and *Giardia* in water samples have been described. Detection of mRNA with RT-PCR allows discrimination between viable and nonviable organisms, whereas sequence analysis of RT-PCR fragments results in differentiation on species or genotype level

and enables confirmation of the presence of human pathogenic species. Genetic variation (in environmental samples) can be studied with the aid of a PCR based on sequences of the 18S ribosomal RNA gene of *Cryptosporidium*.

Direct quantitative detection of *Cryptosporidium* and *Giardia* has become within reach with the widespread application of real-time PCR and holds great promise for the near future, but is, however, in the early phases of development.

## Applications

### Model Organisms

The majority of microbiological analyses of water is not aimed at directly detecting pathogens but seek the presence/absence or concentration of model organisms. These can serve two functions:

1. 'Index organisms', to assess potentially dangerous contamination (such as *Escherichia coli* to indicate fecal pollution and consequently that a vast array of potential pathogens might be present).
2. 'Indicator organisms', to assess the efficiency of a treatment process (such as the heterotrophic plate count to indicate the efficiency of disinfection of swimming pool water).

Water quality standards are usually formulated on the basis of model organisms and tests for these organisms also play a major role in the surveillance of water quality and control of treatment processes. The major advantage of model organisms is that they can be detected and enumerated using simple, inexpensive methods that give results in a relatively short period of time. The major drawback is that there is not a single model organism that will give the right answer in all cases; hence, designing monitoring programs and interpretation of data always requires experience and knowledge about local situations. The most important model organisms are those occurring in large numbers in human or animal feces because this is the most important source of pathogens in water.

In practice, not all requirements for an ideal model organism can be fulfilled by one single species, but *E. coli* is the first choice in most cases. This bacterium occurs universally in feces of warm-blooded animals (including humans) and can be detected to a fairly high degree of selectivity by simple, rapid procedures. Lactose fermentation, indole production, growth at 44°C, and  $\beta$ -glucuronidase activity are the key properties for detection and confirmation of this species. In practice, many routine methods aim

only for lactose fermentation at 44°C (the thermotolerant coliform group) or at 37°C (the total coliform group) in culture media containing a selective surfactant. Thermotolerant coliforms are an acceptable alternative index of fecal pollution in most cases, albeit less specific than *E. coli*. The total coliform group comprises members that can occur in soil or on plant material or may even multiply in water. Their use is therefore restricted, e.g., as a sensitive means of detecting failures in system integrity in drinking-water distribution networks.

Because Enteroviruses and (oo)cysts of parasitic protozoa are known to be more resistant than *E. coli* and other coliforms, the absence of these organisms in surface or treated water does not necessarily mean absence of pathogens. Depending on the purpose of the examination and the type of water under study, additional model organisms need to be assessed. These include the fecal streptococci (which have a generally higher resistance than coliforms), the bacteriophages (in particular the F-specific RNA bacteriophages are good models of human enteric viruses), and *C. perfringens* (whose spores withstand disinfection much better than bacterial vegetative cells).

### Pathogens

The direct detection of pathogenic microorganisms, in particular viruses and protozoa, is usually more expensive and time consuming than detection of model organisms and also requires more sophisticated laboratory facilities. For this reason, application of these methods has been limited to research laboratories and to the monitoring programs of larger water quality management organizations in the industrialized world. However, the price and required expertise for analyzing viruses and protozoa is similar to that of analyzing chemical contaminants such as pesticides and chlorination by-products. In view of the known and acute health risks of pathogenic microorganisms in water, there does not seem to be a risk-based justification for not carrying out such analyses.

A wide range of pathogenic bacteria can be detected in water samples, usually by culture methods. Most commonly, quantitative tests are carried out that require several steps: preenrichment (= resuscitation), selective enrichment, isolation by plate culture, identification by biochemical and/or serological tests, and eventually epidemiological typing.

Pathogenic bacteria are increasingly being referred to in international water quality standards, whereas other pathogens that are not of fecal origin (e.g., *Legionella*, *Pseudomonas aeruginosa*) can actively multiply in the water environment and because no

adequate model organisms exist direct detection is required. In Europe, new drinking water legislation requires assessing the risk of infection for consumers of drinking water, based on the number of pathogenic microorganisms in the source water and the elimination capacity of the drinking water treatment processes. Therefore, direct detection of pathogens is increasingly being included in monitoring programs. It may also be of great value in the following situations:

- testing the efficiency of treatment methods and identifying the most appropriate model organism for routine surveillance;
- assessment of survival and transport phenomena in the environment;
- prospective or retrospective epidemiological studies; and
- after correction of calamities.

For these different purposes a great variety of methods is available, but only few have been introduced in laboratories and the use is widespread, whereas the majority is restrictively used by specialized laboratories.

### Introduction

Water enters our daily lives through drinking, irrigation, recreation, food manufacture, in medicines, and medicine manufacture. Water itself cannot be manufactured and the world relies on natural supply. When conditions suit, freshwater populations of microbes and microalgae can explode and threaten public and environmental health if toxic species are present in these blooms. Consequently, the World Health Organization, drinking water authorities, and many environmental agencies have incorporated water quality guidelines for nuisance freshwater algae and microbes and the toxins they produce. Analytical methods for these toxins that support these quality guidelines can be divided into those that identify the toxin through their chemical properties such as molecular weight or chemical structure, or by their biological properties such as toxicity.

### Structure and Properties of Water-Borne Toxins

#### Microcystins

Microcystins (Figure 1A) are cyclic heptapeptides of low molecular weight quite frequently implicated in intoxication events and synthesized by the cyanobacteria genera such as *Microcystis*, *Anabaena*, *Planktothrix*, and *Nostoc*. They contain two unusual amino-acids: N-methyl-dehydroalanine (Mdha) and 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyl-4,6-dienoic acid (ADDA). The most common sequence is D-Ala<sup>1</sup>-L-X<sup>2</sup>-D-Masp<sup>3</sup>-L-Z<sup>4</sup>-Adda<sup>5</sup>-D-Glu<sup>6</sup>-Mdha<sup>7</sup>, where Masp stands for methylaspartic acid and X and Z for two variable

amino acids giving its name to the molecule under the XZ form (such as microcystin-LR where X = leucine and Z = arginine). More than 70 microcystin variants are known to date, most discovered in the last decade using mass spectrometry, especially electrospray ionization (ESI) coupled to tandem mass analyzers or matrix-assisted laser desorption/ionization coupled to time-of-flight analyzers (MALDI-TOF). These techniques allow the determination of structural variations from very low concentrations. These variations can occur on each amino acid but some occur far more frequently in nature, such as the methylation–demethylation of Masp<sup>3</sup> and Mdha<sup>7</sup> acids, or the esterification of glutamic acid in position 6. About half of the known variants are produced by *Microcystis*.

Microcystins generally present two carboxylic acid functions and sometimes some additional basic functions on the variable amino acids (for example, the guanidine function on the arginine of microcystin-LR). Their ionization will therefore vary as a function of the pH. Microcystins are considered water soluble although few solubility data are actually available. Their polarity is variable with octanol–water partition coefficients (log K<sub>ow</sub>) values ranging from 2.2 to 4.4 as estimated by chromatographic analysis, showing that they are rather hydrophobic.

Microcystins potently inhibit serine/threonine protein phosphatases that dephosphorylate other proteins, an action akin to an on/off switch. The novel hydrophobic amino acid ADDA is essential to its bioactivity. Its action also promotes the formation of tumors. The liver is particularly susceptible to these toxins because unlike many other cell types, these peptides readily penetrate liver cells and are specifically taken up through the bile acid transport pathway. These toxins damage the liver by affecting the maintenance by these phosphatases of the cytoskeleton, a network of protein filaments. Protein phosphatases degrade the colorless *p*-nitrophenyl phosphate into a yellow product and this has been

### Introduction

Water enters our daily lives through drinking, irrigation, recreation, food manufacture, in medicines, and medicine manufacture. Water itself cannot be manufactured and the world relies on natural supply. When conditions suit, freshwater populations of microbes and microalgae can explode and threaten public and environmental health if toxic species are present in these blooms. Consequently, the World Health Organization, drinking water authorities, and many environmental agencies have incorporated water quality guidelines for nuisance freshwater algae and microbes and the toxins they produce. Analytical methods for these toxins that support these quality guidelines can be divided into those that identify the toxin through their chemical properties such as molecular weight or chemical structure, or by their biological properties such as toxicity.

### Structure and Properties of Water-Borne Toxins

#### Microcystins

Microcystins (Figure 1A) are cyclic heptapeptides of low molecular weight quite frequently implicated in intoxication events and synthesized by the cyanobacteria genera such as *Microcystis*, *Anabaena*, *Planktothrix*, and *Nostoc*. They contain two unusual amino-acids: *N*-methyl-dehydroalanine (Mdha) and 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyl-4,6-dienoic acid (ADDA). The most common sequence is D-Ala<sup>1</sup>-L-X<sup>2</sup>-D-Masp<sup>3</sup>-L-Z<sup>4</sup>-Adda<sup>5</sup>-D-Glu<sup>6</sup>-Mdha<sup>7</sup>, where Masp stands for methylaspartic acid and X and Z for two variable

amino acids giving its name to the molecule under the XZ form (such as microcystin-LR where X = leucine and Z = arginine). More than 70 microcystin variants are known to date, most discovered in the last decade using mass spectrometry, especially electrospray ionization (ESI) coupled to tandem mass analyzers or matrix-assisted laser desorption/ionization coupled to time-of-flight analyzers (MALDI-TOF). These techniques allow the determination of structural variations from very low concentrations. These variations can occur on each amino acid but some occur far more frequently in nature, such as the methylation–demethylation of Masp<sup>3</sup> and Mdha<sup>7</sup> acids, or the esterification of glutamic acid in position 6. About half of the known variants are produced by *Microcystis*.

Microcystins generally present two carboxylic acid functions and sometimes some additional basic functions on the variable amino acids (for example, the guanidine function on the arginine of microcystin-LR). Their ionization will therefore vary as a function of the pH. Microcystins are considered water soluble although few solubility data are actually available. Their polarity is variable with octanol–water partition coefficients (log *K*<sub>ow</sub>) values ranging from 2.2 to 4.4 as estimated by chromatographic analysis, showing that they are rather hydrophobic.

Microcystins potently inhibit serine/threonine protein phosphatases that dephosphorylate other proteins, an action akin to an on/off switch. The novel hydrophobic amino acid ADDA is essential to its bioactivity. Its action also promotes the formation of tumors. The liver is particularly susceptible to these toxins because unlike many other cell types, these peptides readily penetrate liver cells and are specifically taken up through the bile acid transport pathway. These toxins damage the liver by affecting the maintenance by these phosphatases of the cytoskeleton, a network of protein filaments. Protein phosphatases degrade the colorless *p*-nitrophenyl phosphate into a yellow product and this has been

**Figure 1** Structures of (A) microcystin-LR, (B) cylindrospermopsin, (C) anatoxin-a, (D) anatoxin-a(S), and (E) saxitoxin.

used to develop an enzyme inhibition assay for these toxins. Fluorescent substrates for protein phosphatases also exist now. Protein phosphatase isoforms sensitive to the microcystins are readily available from both commercial and natural sources. A variety of antibodies have been generated to microcystins that have been incorporated into enzyme-linked immunosorbent assays. This very large family of toxins and the subsequent variety in their chemical properties is problematic, however, in that antibodies targeting the peptidic portion of their structure are not likely to possess significant cross-reactivity to the multitude of microcystin variants. This has been circumvented in part by producing antibodies targeting the structurally invariant ADDA functionality common to all microcystins.

### Cylindrospermopsin

Cylindrospermopsin ( $C_{15}H_{21}N_5O_7S$ ; MW = 415.4), synthesized by the blue-green algae, *Cylindrospermopsis raciborskii*, *Umezakia natans*, and *Aphanizomenon ovalisporum*, presents a chemical

structure radically different from peptidic hepatotoxins (Figure 1B). It is an alkaloid consisting of a tricyclic guanidine moiety combined with hydroxymethyluracil. Zwitterionic, highly water soluble, and stable at acidic pH, does not degrade at 100°C for 15 min. An epimeric form (hydroxy group) can also be detected as well as a mildly toxic desoxycylindrospermopsin variant, as measured in mice.

Cylindrospermopsin's existence was first realized after 149 people were poisoned on Palm Island off the north-east Australian coastline when their fresh-water dam became contaminated by *C. raciborskii*. The molecular mechanism by which this toxin exerts its toxicity is yet to be elucidated. Liver toxicity, however, is the main toxic manifestation but lesions in the kidney, heart, and thymus occur when tested on mice and rats. Orally, cylindrospermopsin has a median lethal dose to mice of  $6 \text{ mg kg}^{-1}$  whereas intraperitoneal injection of mice yields an  $LD_{50}$  of  $0.2 \text{ mg kg}^{-1}$ . Other whole organism assays used to measure cylindrospermopsin toxicity include the brine shrimp *Artemia salina* ( $LD_{50} = 0.7 \mu\text{g ml}^{-1}$  after 72 h) and the crustacean *Thamnocephalus platyurus*,

used in the commercially available Thamnotox kit. Plants too have been used to test for cylindrospermopsin as it inhibits the growth and metabolism of the mustard plant *Sinapis alba*.

Not surprisingly, the toxin's liver toxicity is reflected by the ability of micromolar concentrations of cylindrospermopsin to kill *in vitro* liver cells such as rat hepatocytes and the human hepatoblastoma cell line HEP-G2. Cylindrospermopsin is known to potentially inhibit cellular protein synthesis that can be measured *in vitro* using rabbit reticulocyte lysate.

## Anatoxins

Anatoxins are alkaloids produced exclusively by the cyanobacterial genera *Anabaena*, *Planktothrix*, and *Aphanizomenon*. Anatoxin-a (Figure 1C), the first cyanobacterial toxin to be chemically and functionally characterized in 1972, is a secondary amine whose ionization state varies with the pH ( $pK_a = 9.4$ ). This compound is highly polar and fully soluble in water. Its methylated derivative homoanatoxin-a presents very similar properties. At elevated pH (above 10), both toxins become unstable and degrade very quickly into nontoxic analogs.

Anatoxin-a is a potent nerve toxin that acts postsynaptically. Synapses are a physical gap between nerves, and nerve and muscles, which must be traversed by any nerve impulse. This is achieved by the neurochemical acetylcholine moving across the synaptic junction. On the receiving side of a synapse, one finds acetylcholine receptors in the cell membrane that open when they bind acetylcholine to allow the entry of many ions into the nerve or muscle. Increased intracellular cations depolarize the receiving cell triggering a cascade of events that continue the action potential. Anatoxin-a is a powerful agonist of acetylcholine receptors being many times better than acetylcholine itself in stimulating the receptor to open. Anatoxin-a therefore outcompetes and displaces acetylcholine overstimulating the receptor, impairing its function and incapacitating nerve and muscle.

Acetylcholine receptors can be prepared from a variety of excitable tissues from animals. An example is the electric organ of electric eels, a very dense concentration of excitable tissue and a source of many neuronal receptors. A number of other chemicals competitively bind with anatoxin-a for the acetylcholine receptor (e.g., nicotine, acetylcholine itself,  $\alpha$ -bungarotoxin) and have been radiolabeled and used in receptor binding assays for anatoxin-a.

To date, anatoxin-a(S) is the only known natural organophosphate inhibitor of the neuronal enzyme acetylcholinesterase. The freshwater environment

can also be contaminated by insecticides such as parathion and malathion, which are also organophosphates that act in the same manner as anatoxin-a(S). With a structure (Figure 1D) very different from anatoxin-a, anatoxin-a(S) is rarely encountered and very little is known about its properties owing to strong chemical instability.

As described above, acetylcholine carries the signal across the gap between nerves and nerve to muscle. If acetylcholine lingered in the synaptic gap it would continually stimulate the acetylcholine receptor and the enzyme acetylcholinesterase degrades the acetylcholine. Anatoxin-a(S) inhibits acetylcholinesterase preventing the removal of acetylcholine and nerve and muscle cells become hyperexcited. Mice injected intraperitoneally with anatoxin-a(S) excessively salivate and exhibit lacrimation, urinary incontinence, defecation, convulsion, fasciculation, and die by respiratory arrest. By this route, the toxin has an  $LD_{50}$  approaching  $50 \mu\text{g kg}^{-1}$ .

Anatoxin-a(S) can therefore be measured by its inhibition of acetylcholinesterase whose enzyme activity can be measured by several ways. One example is its degradation of the acetylcholine analog, acetylthiocholine, and subsequent measurement of the released thiocholine by the sulfur reacting chemical Ellman's reagent. Acetylcholinesterase has been cloned and its mutation can increase the enzyme's sensitivity for anatoxin-a(S). Combining different acetylcholinesterase mutants with divergent specificity for anatoxin-a(S) and the above-mentioned organophosphate insecticides has enabled better analyte discrimination. This multiple enzyme method has been implemented in a biosensor that carries several of the acetylcholinesterase mutants.

## Saxitoxins

Saxitoxin ( $\text{C}_{10}\text{H}_{17}\text{N}_7\text{O}_4$ ;  $\text{MW} = 299$ ) was first isolated from the marine environment, namely from the clam *Saxidomus giganteus* from whence it derives its name. Saxitoxin (Figure 1E) has more than 25 naturally occurring chemical variants, all of which are tricyclic molecules with the 1,2,3- and 7,8,9-guandinio groups of STX itself possessing  $pK_a$ s of 11.3 and 8.2, respectively. They are all substituted tetrahydropuric bases, water soluble, thermostable and stable in acidic conditions. However, they are unstable in alkaline conditions and sensitive to oxidative conditions. Most derivatives present a common backbone, saxitoxin or *N*-hydroxysaxitoxin, and only differ on the location and number of sulfate substitutions. However, a new class of toxins has recently been discovered, with a phenolic group in place of the typical sulfate substitution. In the freshwater

environment, they can be produced by the cyanobacteria *Aphanizomenon flos-aquae*, *Anabaena circinalis*, *Lyngbya wollei*, and *Cylindrospermopsis raciborskii*. As expected from their chemical structure, these toxins have very different polarities and their lack of chromophore complicates their analysis.

The longest used bioassay for the saxitoxin family is intraperitoneal injection of mice, with toxin quantitated by comparing the time to death from respiratory paralysis to a standard series of mouse units. Saxitoxin is highly toxic, being lethal to guinea pigs at only  $5 \mu\text{g kg}^{-1}$  when injected intramuscularly and at similar doses when injected intraperitoneally into mice. Saxitoxin blocks sodium ion entry into nerves and muscle by occlusion of the voltage gated sodium channel. This prevents the conduction of a cellular action potential, paralyzing any victim, sometimes fatally.

A variety of *in vitro* assays have been developed that minimize or avoid live animal experimentation. Several capitalize on the sodium channel's affinity for these toxins. Neuronal cell lines lyse in the presence of veratridine, a sodium channel activator, and ouabain, which prevents removal of the excessive sodium ions allowed in by veratridine. In the presence of both these drugs, a sodium channel blocker such as saxitoxin rescues the cells. Cellular viability can then be measured by adding tetrazolium salts that are metabolized by living cells to a colored product. Alternatively, isolated cellular membranes, typically from brain tissue, are used to bind radiolabeled saxitoxin. After incubating receptor and radioligand in the presence of a test sample, any radiolabeled saxitoxin bound to the cell membranes are deposited onto filters by vacuum pressure. Radioactivity from the labeled saxitoxin is then measured with a signal reduction indicating the presence of saxitoxin.

Saxitoxin is also bound by receptors unrelated to the sodium channel. The first is saxiphilin, a protein found in the circulatory fluid of many animals used in a receptor binding assay much like that described above for the sodium channel. An alternative to natural receptors is to generate antibodies to saxitoxin. Saxitoxin itself does not elicit an immune response from mammals and one does not want the animal used to generate the antibodies to die from the toxin. The toxin then is linked to a carrier protein to create an antigenic epitope and reduce its toxicity. An example carrier is the enzyme horseradish peroxidase, which can also be used to generate an assay signal from the enzyme converting a colorless substrate to a visible product. Saxitoxin will interfere with the binding between the saxitoxin-horseradish peroxidase conjugate and the antibody generated to the toxin-protein complex and reduce any assay signal. Such

assays, however, are servant to the fact that antibodies raised toward one member of the saxitoxin family may not detect other chemical relatives.

## Extraction, Concentration, and Purification of Water-Borne Toxins

Most cyanotoxins are secondary metabolites that stay inside the cells during the growth phase and are released in the extracellular medium following cell lysis. In the environment, the concentration of toxins in the water is generally very low and the determination of the toxic potency is often facilitated by the analysis of the cells themselves or by preconcentrating the dissolved toxins by solid-phase extraction (SPE).

### Intracellular Toxins

Because cells are usually rich in proteins, minimizing their co-extraction using acetic acid at 5% (v/v) can be valuable. However, the choice of the extraction solvent will first depend on the polarity and solubility of the target toxins. The absolute efficiency of the extraction process can only be calculated using certified matrices, which are only available for a few toxin types. In the absence of such reference materials, several extraction methods can be tested and compared to identify the most efficient technique.

Microcystins have been extracted from cyanobacterial cells using aqueous acetic acid, various hydroalcoholic mixtures including the very popular *n*-butanol-methanol-water (5/20/75; v/v), but also methanol, pure or acidified with trifluoroacetic acid. If the extraction solvent was to contain too much water, the most hydrophobic toxins would be poorly extracted as a result of their low solubility in such a solution, and vice versa. Supercritical fluid extraction has also been applied to microcystins using 90% CO<sub>2</sub>, 9% methanol, and 1% water as the supercritical fluid.

Cylindrospermopsin is readily extracted with methanol or aqueous acetic acid.

As a result of its high polarity, anatoxin-a is better extracted in aqueous solutions. Aqueous solutions with or without acid have been employed, as well as water-alcohol mixtures. Anatoxin-a is volatile and can be lost during evaporation phases. Minimizing the extraction volumes and shortening evaporation steps can therefore increase extraction yields.

Anatoxin-a(S) has been extracted into acidified ethanol or a mixture of ethanol-aqueous acetic acid  $0.05 \text{ mol l}^{-1}$ .

Saxitoxins present a similar polarity to anatoxin-a and are extracted with aqueous acetic acid or

hydrochloric acid (pH 3) mixed with some alcohol, using ~50 ml of extraction solvent per gram of cells.

### Toxins Dissolved in the Water

When dissolved in the aqueous medium, toxins can be isolated by liquid–liquid extraction or liquid–solid extraction also called SPE. Liquid–liquid extraction consumes relatively large amounts of organic solvent and is not suitable for the extraction of water-soluble toxins and will not be discussed here.

The mechanism of SPE is directly related to liquid chromatography: toxins have to be retained by the adsorbent and not eluted by the water in the sample. Extraction sorbents are therefore similar to those used in liquid chromatography, reversed-phase (*n*-alkyl silica, apolar copolymers, graphitized carbon) for aqueous samples, or ion exchangers for charged compounds. Extraction parameters can be directly extrapolated from the retention times of the analytes as measured by liquid chromatography with water as the mobile phase.

In order to be able to detect very low concentrations of toxins in the water, volumes of about a liter of water can be concentrated employing disposable SPE cartridges. *N*-Octadecyl silica (C18) is by far the most common sorbent for the extraction of neutral, mildly polar, or hydrophobic organic compounds, and is excellent for microcystins concentration. However, it does not allow for an efficient extraction of polar toxins such as anatoxin-a, saxitoxins, or even cylindrospermopsin.

In contrast to intracellular toxins, estimating the extraction yields in water is made easier by our ability to spike the samples with known concentrations of standard toxins. As far as microcystins are concerned, the most adopted extraction protocol involves the acidification of the samples with trifluoroacetic acid before percolating them through a disposable C18 SPE cartridge. Polar variants such as microcystins RR, YR, or LR are still hydrophobic enough for 500 ml of aqueous sample to be percolated through a 500 mg C18 SPE cartridge without decreasing the overall recovery, even at neutral pH. Adding ~5% of methanol to the samples also prevents the adsorption of more hydrophobic microcystins to the plastic walls and help maximizing their recovery. The elution of microcystins from the SPE cartridges can be carried out with a few milliliters of acidified methanol (1% of trifluoroacetic acid, for example). A washing step can also be introduced just before the elution using a few milliliters of 20% methanol to eliminate weakly retained interferants. Detection limits of 0.05 and 0.1  $\mu\text{g l}^{-1}$  can be

reached for individual microcystins in drinking water and surface water, respectively.

Extraction of anatoxin-a is made more difficult by its strong polarity and protonation at pH below 9.4. The retention properties and as a consequence the volume of sample percolated can be improved by working in alkaline conditions where the toxin becomes neutral. An alternative is to use XAD2 resin after adjusting the toxins to pH 10.5. The use of extraction cartridges filled with styrene divinylbenzene (SDB) copolymers could drastically improve the SPE of anatoxin-a. As a matter of fact, these materials present a very large activated surface area and it has been shown that they extract many polar pesticides, even in their ionized form, although those same molecules were not extractable using typical C18 SPE cartridges. It has been found that up to 500 ml of water spiked with anatoxin-a (without pH adjustment) could be percolated onto a 200 mg SDB cartridge without observing any recovery loss. Elution was performed with 5 ml of acidified methanol (0.01% HCl), before evaporating the sample under nitrogen flux to a 100  $\mu\text{l}$  residual volume (avoiding a complete drying of the sample helps maintain high recoveries). Using this protocol, limits of detection of 0.1 and 0.3  $\mu\text{g l}^{-1}$  could be achieved starting with a 500 ml sample of drinking water and surface water, respectively.

Extraction of saxitoxins or cylindrospermopsin from aqueous samples has not been much described. Regarding their strong polarity, copolymers described earlier for anatoxin-a or graphitized carbon should give good results. The latter material is commonly used to desalt saxitoxin samples, but has also been shown to allow the extraction of cylindrospermopsin from lake waters spiked at 1  $\mu\text{g l}^{-1}$ .

### Immunoextraction

The SPE methods described above are all based on nonspecific interactions. Immunoextraction, on the other hand, is based on the high affinity of antibodies for a class of antigens, allowing their highly selective extraction from even very complex matrices. The covalent linkage of antibodies to various solid supports has allowed the development of SPE cartridges for a number of compounds. Some of these cartridges are commercially available such as those used for mycotoxins purification: aflatoxins, ochratoxins, and zearalenone. Antimicrocystin-LR monoclonal antibodies have been used to extract microcystins from environmental matrices, providing simultaneous concentration and purification of water samples.

## Chromatographic Analysis of Toxins

Chromatographic methods are routinely applied to the detection and quantification of toxins. Gas-phase chromatography (GPC) is not well adapted to non-volatile microcystins and requires chemical derivatization steps for other toxins; however, its ability to be directly coupled to mass spectrometers makes it a powerful tool. Capillary electrophoresis coupled to mass spectrometry has also been applied to the analysis of microcystins and saxitoxins. Although it seems to present several advantages over other techniques, it remains at a developmental stage as far as toxins are concerned.

### Gas-Phase Chromatography

Microcystins are not volatile and have to be chemically fragmented to be analyzed by GPC, for example, by oxidizing the ADDA fragment common to all microcystins and forming the 2-methyl-3-methoxy-4-phenylbutyric acid. When coupled to a mass spectrometer, this technique allows the measure of nanogram amounts of total microcystin in less than 30 min.

Anatoxin-a has to be derivatized using chemicals such as *t*-butyldimethylsilyl or pentafluorobenzyl bromide and 0.1–0.5 ng amounts can then be detected.

### Liquid-Phase Chromatography

As discussed previously, microcystins are quite hydrophobic and most analyses are performed by reversed-phase liquid chromatography (LC), and most often using octadecylsilica as a stationary phase and a mixture of water and acetonitrile as mobile phase. The latter can be acidified (e.g., with 0.03% trifluoroacetic acid) and a 30–80% acetonitrile gradient allows the elution of most microcystins of various polarities. Separations are usually followed by ultraviolet (UV) detection, since all microcystins can absorb at 238 nm. Some additional maxima at 223 and 232 nm for tryptophan- and tyrosine-containing microcystins can be observed, justifying the use of a photodiode array UV detector. Additional coupling of LC to mass spectrometry has greatly enhanced the rate of microcystins discovery, especially since the ESI interface was introduced and shown to be ideally suited to microcystins analysis. MALDI-TOF mass spectrometry has been used to screen for and characterize microcystins from various environmental samples showing very promising results.

Cylindrospermopsin is a polar compound, retained sufficiently however on C18 phases to be analyzed by reversed-phase LC. As an example, its retention time is ~16 min using a Spherisorb ODS-2 column with a 10 min linear gradient from 0 to 5% methanol

followed by 10 min at 5% methanol. Common detection techniques are UV absorbance (262 nm) or electrospray mass spectrometry (ion at  $m/z = 416$  Da).

Anatoxin-a can be analyzed by reversed-phase LC using a C18 stationary phase and an isocratic mobile phase containing only small amounts of acetonitrile or methanol. Common detection techniques are UV (227 nm) or electrospray mass spectrometry (ion at  $m/z = 166$  Da) (Figure 2).

Saxitoxins do not carry any chromophore and are not detectable by measuring UV absorbance. The most reliable analytical method so far is based on an ion-pairing chromatographic separation followed by postcolumn chemical oxidation and fluorescence detection. The mobile phase is a mixture of water and acetonitrile containing sodium *n*-alkylsulfonate as an ion-pairing agent, and three different isocratic runs are usually performed to reliably separate and quantify saxitoxins from all three classes: saxitoxin, gonyautoxins, and C-toxins. Considering the large number of saxitoxins variants to be detected (>25), systematic coupling of LC to electrospray mass

**Figure 2** An example of the analysis of a water-borne toxin combining several of the procedures outlined in the text. Analysis of culture medium of the freshwater cyanobacterium *Anabaena* sp. 86 by LC–photodiode array detection following a concentration step on SDB SPE cartridges (inset: UV spectrum of anatoxin-a). Experimental conditions: C18 column; mobile phase: acetonitrile (2.5%)/potassium phosphate 5 mmol l<sup>-1</sup>, pH 3.5 (97.5%).

spectrometry is the most efficient technique. However, the mobile phases described above are not compatible with mass spectrometry interfaces and a new protocol has been developed involving the separation of saxitoxins using hydrophilic interaction chromatography, which can then be coupled to a mass spectrometer. The complete range of saxitoxin variants can be detected and quantified in a single chromatographic run.

## Bacterial Endotoxin

Primarily of interest to those requiring high-quality water for the manufacture of pharmaceuticals and biologicals, but emerging as an issue for natural water supplies is bacterial endotoxin, a lipopolysaccharide released when the cell walls of Gram-negative bacteria lyse. In humans, endotoxin release can lead to sepsis and septic shock. Fortunately, there exists a reliable and validated method based on the *Limulus* amoebocyte lysate assay. *Limulus polyphemus* is a horseshoe crab whose circulatory fluid rapidly coagulates when endotoxin is present. Coagulation

is caused by a protein in the amoebocytes in the horseshoe crab blood. Endotoxin quantitation is achieved by measuring various parameters of the clotting reaction such as simple measurement of turbidity or the more sophisticated use of chromogenic substrates that react to the responsible enzyme in the presence of endotoxin.

## Introduction

There is a well-established literature on particle analysis with respect to stable nonliving particles and living biological entities that can be considered as particles in the analysis of natural waters. The gross characteristics of aquatic particles larger than 1  $\mu\text{m}$  are relatively well known in terms of chemical nature and size distribution. A literature of similar quality and extent for unstable aquatic particles, especially those in the colloidal size range (1 nm to 1  $\mu\text{m}$ ), is currently being developed. The unstable particles of greatest interest in this endeavor are colloid systems (organic, inorganic, and mixed) that change their physical nature (size, shape, porosity) upon perturbation, especially after perturbations that disturb water molecules intimately associated with the structural integrity of a colloid system. Examples are macromolecular gels, growing flocs, and aggregating surface-active molecules. The focus

of this article will be on such unstable particulate materials.

The emerging literature on unstable aquatic particles stresses minimally perturbing analyses of minimally perturbed sample preparations. It treats native colloids and colloid systems as materials possessing their own intrinsic properties in the complex aquatic media from which they are sampled. Through the use of multimethod approaches, such minimally perturbed materials can be characterized according to their native state, as opposed to degraded (dehydrated, oxidized, coagulated, extracted, shrunken, or altered by microbes) versions of them. Concomitant with improvements in descriptive techniques have come refinements in the systematic means for detecting, minimizing, and assessing artifacts of colloid instability. Essential to producing the most detailed characterizations is analytical electron microscopy (AEM) used in concert with the particle analysis methodology of physics and analytical chemistry, and with novel advances in sample stabilization. With AEM, different kinds of microscopes and accessories are used in a correlative manner and transmission electron microscopy (TEM) is the principal instrument for structural analysis.

spectrometry is the most efficient technique. However, the mobile phases described above are not compatible with mass spectrometry interfaces and a new protocol has been developed involving the separation of saxitoxins using hydrophilic interaction chromatography, which can then be coupled to a mass spectrometer. The complete range of saxitoxin variants can be detected and quantified in a single chromatographic run.

## Introduction

There is a well-established literature on particle analysis with respect to stable nonliving particles and living biological entities that can be considered as particles in the analysis of natural waters. The gross characteristics of aquatic particles larger than 1  $\mu\text{m}$  are relatively well known in terms of chemical nature and size distribution. A literature of similar quality and extent for unstable aquatic particles, especially those in the colloidal size range (1 nm to 1  $\mu\text{m}$ ), is currently being developed. The unstable particles of greatest interest in this endeavor are colloid systems (organic, inorganic, and mixed) that change their physical nature (size, shape, porosity) upon perturbation, especially after perturbations that disturb water molecules intimately associated with the structural integrity of a colloid system. Examples are macromolecular gels, growing flocs, and aggregating surface-active molecules. The focus

of this article will be on such unstable particulate materials.

The emerging literature on unstable aquatic particles stresses minimally perturbing analyses of minimally perturbed sample preparations. It treats native colloids and colloid systems as materials possessing their own intrinsic properties in the complex aquatic media from which they are sampled. Through the use of multimethod approaches, such minimally perturbed materials can be characterized according to their native state, as opposed to degraded (dehydrated, oxidized, coagulated, extracted, shrunken, or altered by microbes) versions of them. Concomitant with improvements in descriptive techniques have come refinements in the systematic means for detecting, minimizing, and assessing artifacts of colloid instability. Essential to producing the most detailed characterizations is analytical electron microscopy (AEM) used in concert with the particle analysis methodology of physics and analytical chemistry, and with novel advances in sample stabilization. With AEM, different kinds of microscopes and accessories are used in a correlative manner and transmission electron microscopy (TEM) is the principal instrument for structural analysis.

## Colloids

### General Aspects

In the context of aquatic environments, there is no clear definition of a colloid. For practical purposes, a colloid is considered to be any particle whose least dimension is within the colloidal size range, with the upper limit often being defined by a filtration operation. As a result of their very small size, colloids have properties intermediate between solutes and conventional particles, tending not to settle out of 'solution' unless they have become part of a settling aggregate much larger than 1  $\mu\text{m}$ . While the smallest colloids tend to aggregate strongly, individual colloids can persist as suspended units. When individual units associate into a colloid system, the resultant material takes on properties intrinsic to the material *per se*. Such a colloid system can aggregate or disaggregate in response to relatively minor perturbations of its aquatic milieu. Thus, an individual colloid can alternate from being a solute to being a component of a settling aggregate (a conventional particle). Because aquatic colloids are implicated strongly in the dispersion and fate of environmental contaminants, there is an urgent need to understand better their roles and behavior. As a result of their physical instability, however, they present challenges to attempts at realistic (native state) characterizations.

Colloids common to aquatic ecosystems are quite varied. They can be living (unicellular bacteria) or nonliving; the nonliving types can be organic (secreted fibrils and other refractory extracellular materials, fragmented cell parts, humic substances), inorganic (clay minerals, iron and manganese oxyhydroxides, silicates), or mixed (organic coatings on mineral colloids, mineral precipitates on organic fibrils or bacterial cell walls). Different combinations of the common colloids can coaggregate, sometimes under biological influence, to give rise to mixed materials such as microbe-rich flocs, mixed mineral sediments, and these two classes 'blended' together.

An example of a relatively simple colloid system (natural association of colloids), prepared for quantitative TEM analysis in a minimally perturbing way, is shown in **Figure 1**. It is rich in partially dispersed fibrils (elongated organic structures rich in acid polysaccharide) that tend to aggregate, so as to convert spontaneously into densely packed sheets, when their hydration status is perturbed by prolonged storage in water or by freeze-drying prior to receipt by an analyst. When the system's pore structure collapses as a result of sample mishandling, the fibrils and associated colloids tend to be incorporated into an (artifactual) dense gel, with concomitant reorientation of native associations (via uneven shrinkage) and the occlusion

of some colloids deep within a near-impermeable organic matrix (impermeable to some extractants used by water quality analysts). **Figure 1** is chosen as an example of an interesting colloid system because of two features. Because it is a relatively large association of colloids, it reveals the flattening artifact caused by the capture of a heterogeneous, highly hydrated, aquatic particle onto a (transparent film mounted on a) TEM grid. Secondly, despite the flattening, this 'whole mount' preparation was amenable to a quantitative image analysis of the relative frequency of colloid morphotypes.

Artifactual aggregation of many kinds of colloids can occur at surfaces within apparatus used for water fractionation and fraction concentration. In addition to the artifacts resulting from mild mishandling, one must consider the artifacts produced by deliberate harsh treatments devised in the past to allow a high degree of purification of a given component of a natural water (such as clay minerals, biogenic minerals, and undenatured humic substances). Such harsh treatments as exposure to corrosives and exposures to multiple extractants destroy native associations and reduce complex materials to their most refractory components (e.g., 'cleaned' minerals, 'operationally defined' humic substances). Minimal sample perturbation in preparation for AEM is a necessity for characterizing native colloid associations.

### The Nature of the Data

To the greatest extent feasible, a characterization should be based on hydrated samples or samples stabilized in a hydrated configuration. While developing the data collection, one must take into account the dynamic properties of colloids that dominate their behavior in nature and that provoke those artifacts whose quality and extent should be known by the analyst. To the greatest extent feasible there must be a strong emphasis on analyses that are done on a 'per colloid' basis. The nature of the potentially available data for 'aggregated' colloids (and for particles in general) from research centered on TEM analyses is as follows: shapes; sizes and size distributions per aggregate type; porosity and density of packing, including patchiness; relative frequency of colloid types; three-dimensional arrangement of colloid types; fractal dimensions; and quantification of frequent natural associations.

Such data are derived by correlating morphological analyses (on a 'per colloid' basis), obtained by TEM, with information from the following techniques: elemental composition analysis using scanning transmission electron microscopy coupled to energy dispersive spectroscopy (STEM-EDS); TEM-based

**Figure 1** A transmission electron micrograph of a whole mount prepared, by ultracentrifugation, from a water sample rich in colloids, accompanied by images derived from computerized image analysis. (A) The original electron micrograph showing fibrils F, a microcolony of bacteria B, small mineral colloids associated with the meshwork of fibrils, and organic debris (electron-translucent structures at extreme lower left). (B) An image showing all colloids more electron-dense than the fibrils. (C) An image showing only fibrils. (D) A composite of the two images from 'B' and 'C'. The scale bar corresponds to 0.45  $\mu\text{m}$ . (Reproduced with permission from Leppard GG and Arsenault AL (2003) Quantification of individual native biocolloids in natural waters: Assessing indicators of aquatic events, by using transmission electron microscopy with a modified approach to image analysis. *Archiv fuer Hydrobiologie*, 156: 565–573, <http://www.schweizerbart.de>.)

selected area electron diffraction (SAED); electron energy loss spectroscopy (EELS) used with energy filtered TEM; atomic force microscopy (AFM); microchemistry (certain techniques modified by biomedical scientists for use with EM preparations); and highly selective probes modified to make them electron-opaque (e.g., by attaching distinctive gold colloids to them). Correlating standard TEM information with that of (synchrotron-based) scanning transmission X-ray microscopy (STXM), applied to the same particle, has begun; STXM provides information on the atomic environment of a given element and permits mapping of chemical species based on bonding structure. Elemental composition analyses by STEM–EDS can be done on both a colloid system basis (e.g., dot mapping) and on a per colloid basis (for individuals in the mid-size range and larger).

Crystallographic ‘fingerprinting’ of even small colloids can be achieved with SAED of crystalline colloids placed in the specimen plane of a TEM. To a limited extent, microchemistry can reveal the heterogeneous distribution of families of molecules, particularly organic macromolecules. The selective staining of such molecules with distinctive molecular markers has been developed into a fine art to differentiate subcomponents of heterogeneous particles. Information from EELS can complement that from EDS, especially for identifying light elements with a high spatial resolution; EELS can also provide qualitative information about the molecular environment of an element. AFM permits very high resolution of hydrated macromolecules.

Particle analysis techniques independent of EM-based techniques can be used to verify and extend

some of the EM data in multimethod correlative experiments. They can, of course, be employed profitably with no reference to EM in the analysis of aquatic colloids where limited kinds of information (e.g., size distributions of near spheres) are all that one requires. Among the most informative of the technologies are field-flow fractionation (FFF), fluorescence correlation spectroscopy (FCS), photon correlation spectroscopy, ultracentrifugation, and (when 'tuned' by trial-and-error experimentation to minimize colloid aggregation artifact) filtration/ultrafiltration.

The nature of the data required by aquatic scientists in the past tended to be that of particle size and size distributions, approximate particle volumes and shapes, and compositional analyses of a preliminary nature; the information needs of today require much more than this. Techniques unrelated to EM can obtain their data much faster than EM can produce it, concomitantly producing rapid assessments of statistical significance. This past slowness of data production by EM, however, has been overcome partially by specialized image analysis techniques and (for the largest colloids and smallest conventionally defined particles) automated data collection. Use of EM with selected rapid techniques in a correlative manner can accelerate EM data collection while providing necessary details on spatial and chemical heterogeneity unobtainable by rapid techniques. The reluctance on the part of some physical scientists to use EM as a primary tool is based on past unpleasant experiences with a complex, unfamiliar preparative technology whose simplest versions led to uncontrolled artifacts of dehydration. Given the great refinements in EM cryotechnology now at one's disposal and the adaptation of hydrophilic embedding resins for field use, such reluctance is counterproductive. Given a sound and systematic approach to minimal perturbation, the finest details supplied by EM analyses are more amenable to interpretation.

## Large Macromolecules

Macromolecules are defined here in terms of colloids rather than as large solutes. They can be considered generally as small colloids ( $\sim 1$ – $10$  nm), although it is accepted that some mineral colloids and extensively cross-linked biological debris could be considered as macromolecules whose size extends from the small colloid range into the range of conventionally defined particles. FFF in its flow modification can produce particle sizing data ( $1$  to  $>100\,000$  nm) over the entire colloidal size range and extending well into the 'true' particle size range. It can also yield relative molecular mass distributions for macromolecules.

The sedimentation modification of FFF is currently finding success in the separation and size characterization of aquatic colloids and macromolecules in the range of  $10$ – $1000$  nm. These and other rapid sizing techniques for macromolecules can be sufficient in themselves for many research purposes and take a leading role, with EM providing accessory information.

For small aggregates of macromolecules (organic fibrils, some iron polymers), the shape and least diameter of near-nanometer fibrous and acicular structures might best be measured by TEM (although AFM should also be considered). For samples in which one must ascertain native associations within a suspended mixed aggregate, especially when the aggregate is a physically unstable floc, TEM can become an analytical necessity. **Figure 1** illuminates the utility of TEM, and associated image analysis, for recording and quantifying an organic-rich association of colloids that has been captured and stabilized on a support film. The finest components of this porous aggregate (fibrils of  $5$  nm diameter) extend into the macromolecular size range; the fibrils themselves can be linear aggregates of macromolecules.

From a quantitative standpoint, the most important macromolecules suspended and/or dissolved in natural waters are humic acids, fulvic acids, polysaccharides, proteins, natural breakdown products of lignins (and lignocellulose), and cross-linked macromolecular mixtures (of various combinations of the above in differing proportions). Associated with, or bonded to, these mixtures are varying proportions of mineral particles that, in the macromolecular size range, may be either erosion products or the early results of mineral genesis. The humic and fulvic acids of interest to aquatic scientists are, increasingly, the undegraded native versions and not the 'simplified' molecules taken from a chemist's bottle for model studies. The polysaccharides have not yet received the attention that their activities merit, but it is clear that several families of them are (at least on an episodic basis) of quantitative significance. Depending on site and temporal considerations, surface waters can receive important contributions from various acid polysaccharide types (carboxylated or sulphated), cellulose, chitin, and readily decomposed food reserves released from damaged cells (starches, laminarans). Additionally, in localized portions of water bodies, one may find significant quantities of decomposing biota that are releasing other macromolecular substances; among these are organic phosphates (nucleic acids), lipids (lipoprotein complexes), and tannins (tannin-protein complexes).

## Sampling and Sample Preparation

To characterize a sample in a state as close to the native as is possible, one must manipulate the sample as little as is feasible; this usually requires developing a carefully considered sampling strategy that must be linked to all other sample handling steps whether they be in the field or in the laboratory (or even within the analytical instrument). A minimal perturbation approach consists of close adherence to the following general strategy for sampling and sample stabilization/preservation.

1. Take the sample from nature as gently as possible.
2. Avoid sample storage by analyzing and/or stabilizing the sample immediately in the field.
3. Avoid or at least minimize any concentration of sample components.
4. When fractionation is required, isolate the materials/substances as gently as is feasible while minimizing the number of processing steps.
5. When colloid instability artifacts are evident, use TEM to detect their nature and assess their extent, then use TEM as a monitor to aid method modifications designed to minimize the artifacts (tuning the method to suit the sample).
6. Use extraordinary means (when cost–benefit considerations permit) to take samples that are unusually sensitive to perturbation – means such as *in situ* cascade filtration and the stabilization of near-anoxic samples under their natural oxygen tension.

For characterizing readily perturbed colloid systems, certain preparative activities should be avoided completely (such as freeze-drying, sonication, uncontrolled degassing, uncontrolled/excessively high filtration flow rates, exposure to corrosive fluids, and, last but definitely not least, air drying). The method of sample stabilization must be rapid enough to minimize biological activities leading to undesired changes. Sometimes, sample concentration (by way of specialized apparatus) can be made unnecessary by a judicious use of information on the specific properties of the sample site. Some colloids are concentrated naturally by water bodies into layers (iron oxyhydroxides at the oxic-anoxic interface of a lake) or on an episodic basis into zones ('clouds' of organic fibrils being released by a collapsing bloom of algae). The cost of site monitoring to take advantage of such phenomena can be repaid manifold in terms of reducing the cost of adapting to apparatus-induced artifacts of concentration. Many protocols have been established for the nonmicroscopical rapid techniques of particle analysis. To the extent that a given protocol will introduce preparatory artifacts prior to

measurement, the rapid technique will add information on particle characteristics that deviate from those of native particles. The minimal perturbation approach to sample handling can be summarized succinctly in few words – 'do as little as possible'.

Recently, the literature has received many new methods for capturing and/or stabilizing aquatic colloidal materials to permit high-resolution AEM investigations of them and their natural aggregates. In addition to permitting the resolution of nanoscale ultrastructure, these methods permit element composition analysis (EDS and EELS), crystallographic 'fingerprint' analysis (SAED), and sometimes an analysis of the average 'atomic environment' of a given element (EELS, STXM). Attention is currently focused on methods that employ hydrophilic embedding resins, especially the melamine resin Nanoplast, whose usage has been modeled after existing methods in the biomedical literature. The basic Nanoplast method consists of placing hydrated aquatic materials in the water-rich water-miscible resin, which polymerizes so that the three-dimensional relationships of colloids in the material are fixed by resin polymer bridges prior to the loss of all bulk water in the resin-hardening stage of embedding. Thus, the (previously) physically unstable material cannot shrink or distort in response to the final stages of dehydration; it is presented in the specimen plane of a TEM or STEM as a suspended aggregate held in the plane by an electron-transparent resin matrix. Presentation in the specimen plane is accomplished through the use of either ultrathin sections or an ultrathin film. Nanoplast film techniques have evolved well and present certain advantages over sections; sample preparation is faster and the images (see **Figure 1**) are more amenable to quantitative image analysis in the case of films.

Visualization methods based on the ultramicrotomy of samples embedded in the standard hydrophobic resins permit optimal use of biomedical stain technology for selective staining (selective contrast enhancement) of the individual components within (ultrathin sections of) a colloid system. At a structural resolution near 3 nm, one can relate images from aquatic samples (whose contrast has been enhanced in a standard way) to images from the biological literature, to identify many colloid 'species' (fibrils, viruses, bacteria, refractory cell wall fragments, algal scales, eukaryotic cell debris, biogenic minerals). These standard images, despite the artifacts inherent in the preparatory techniques requisite for hydrophobic embedding, present most entities in the context of known artifacts and, usually, known artifacts whose extent has been either minimized or defined for purposes of interpretation; the highest quality portions of this literature are

invaluable as aids for generating characterizations of aquatic colloids. The images derived from the colloids and colloid systems embedded in hydrophobic resins can be correlated with related images derived from the use of a hydrophilic resin with portions of the same sample; the latter approach provides better structural resolution ( $\sim 1$  nm practical resolution) and better structural fidelity, but suffers from the lack of a properly developed stain technology. This latter defect, however, does not impede the analysis of colloidal minerals embedded in a hydrophilic resin; minerals provide sufficient native contrast for preliminary identification via a TEM-based literature that describes the morphology of various mineral colloids; morphological indicators are readily supplemented by spectra from STEM-EDS and 'fingerprinting' by SAED.

## Analysis

### Interfacing EM with Rapid Techniques

There are many techniques of particle analysis that can provide near-nanometer resolution of particle size. Some of these, however, can be inappropriate for a given sample type; examples are samples requiring an undesirable degree of preconcentration and samples with major components that are elongated to the extent that the concept of equivalent spherical diameter becomes meaningless. When used appropriately, high-resolution sizing techniques are increasingly amenable for routine use, especially those techniques that provide data rapidly. They can, however, be underutilized or misleadingly utilized if they are employed with a sample that lacks the integrity necessary for the analyst to do descriptive work at high resolution. Hence, the earlier emphasis on ascertaining the nature of colloid instability artifact with respect to a given type of surface water sample, and the strong argument put forward for a minimal perturbation approach to sample handling, including sampling strategy. The consequent trial-and-error testing requires the analyst to detect, assess, and minimize artifacts of sample manipulation.

Once the artifact problems have been brought under control, the most informative characterizations will be made with a multimethod approach to sizing and chemistry (one that should include EM analyses of particle shape, internal heterogeneity, porosity, and native associations). The multimethod approach can borrow from chemistry, physics, and biology and make use of existing technology transfer entering limnology and oceanography.

Five kinds of rapid sizing techniques were noted earlier in relation to EM characterizations. Three are

discussed below: they are FFF and FCS on account of their expanding potential, and filtration-based technology because its many artifacts have been so thoroughly addressed. Depending on the research goals, selected standard quantitative techniques of chemistry should be applied to aliquots of both raw samples and fractionated samples, whenever feasible, to provide baseline information on composition. Early compositional analyses via wet chemistry have great utility for interpreting semiquantitative EM data and for selecting tests from the large suite provided by the literature of EM-based microchemistry. In general, where polydispersity confounds the interpretation of rapid analytical techniques, TEM should be employed correlatively as a detective's tool to clarify the problem and add details to existing data. Ultracentrifugation, used effectively for the whole mount preparation displayed in **Figure 1**, has not been developed as much as its potential would indicate for aquatic particle sizing.

To couple EM descriptions (on a per colloid basis) with size distribution data derived from filtration operations, it is necessary to employ a filtration apparatus in a highly controlled manner, so as to minimize operation-induced aggregation. The main contribution to this aggregation artifact is, often, an inappropriate flow rate. As revealed by **Figure 2**, there is an intermediate flow rate window that can be used for size fractionations yielding realistic data on the sizes of polydisperse, unstable colloid systems. In the light of current research needs, it is necessary to delineate this window for a given water type; TEM is essential for doing this well and for characterizing the unperturbed fractions. As a broad generalization, filtration/ultrafiltration is (potentially) a treacherous means for obtaining sizing information on aquatic colloid systems and should not be employed in a straightforward, unmonitored manner. That warning having been voiced, it must also be stated that impressive efforts have been made to identify and then minimize the artifacts of filtration/ultrafiltration, and that much valuable research has come from the application of this technology to natural waters.

FFF is a suite of elution techniques with considerable capacity to separate (by mass, size, charge) an extremely broad range of molecules, macromolecules, colloids, and sedimenting particles. Since the elution patterns are usually recorded by a nondestructive detection method, fractions can be collected for further analyses (chemical, biological, physical) when quantities are sufficient. As a tool for size distribution analyses, it offers many advantages over more conventional techniques for separating substances and materials, one of which is its breadth of applicability (particles may be charged, uncharged,

**Figure 2** A semiquantitative representation of the change in retention of a membrane filter with flow rate due to concentration polarization (high flow-rate domain) and aggregation in the filtration cell (low flow-rate domain). Only an intermediate flow-rate window is usable for size fractionation with a minimal artifact. (Reprinted with permission from Buffle J, Perret D, and Newman M (1992) The use of filtration and ultrafiltration for size fractionation of aquatic particles, colloids and macromolecules. In: Buffle J and van Leeuwen HP (eds.) *Environmental Particles*. IUPAC Environmental Chemistry Series, vol. 1, pp. 171–230. Chelsea, MI: Lewis Publishers; © Lewis Publishers, an imprint of CRC Press, Boca Raton, FL.)

random coil, globular, or fragile). Another advantage is its versatility which derives from the fact that many parameters controlling the separation can be varied precisely over wide limits, allowing one to optimize the range, speed, and power of separation. The range of particle mass to which FFF is applicable is very large, from  $10^3$  to more than  $10^{18}$  Da. As has long been the case for EM analyses of aquatic colloids in ultrathin sections, FFF size analyses were slowed by technical difficulties inherent in working with substances subject to colloid instability. Separations of aquatic colloids and macromolecules are carried out in a thin ribbon-like flow channel by applying a field (or gradient) across the thin dimension of the ribbon-like space and then initiating flow in the channel. Separations are gentle and the interactions of particles with surfaces are minimized. Particle–particle interactions can be minimized when prior sample concentration can be kept near a realistic level.

FCS has been applied only rarely to environmentally relevant aquatic systems, but the technique has a promising future. A major advantage is a high sensitivity that allows the study of native colloids *in situ* at realistic concentrations. It is also selective for specifically labeled molecules, which presents a major advantage for the analysis of chemically heterogeneous media, potentially allowing the study

of formation kinetics and the structure of complex heteroaggregates; a limitation is imposed on its potential by the paucity of naturally fluorescent aquatic colloids and macromolecules. Potential applications include: (1) the study of aggregates and the formation of flocs, known to be significant in the dispersion and transformation of contaminants; (2) analysis of the conformation of fibrillar biopolymers, abundant and active in most surface waters; and (3) the determination of diffusion in complex gels, such as those found at the surface of microorganisms.

### EM Apparatus and Its Correlative Use

While high resolution of structure is essential for many particle analyses, taking full advantage of it can impose a requirement in addition to that of minimal sample perturbation. Individual ultrathin sections and films, under examination by TEM and STEM instruments, pose few problems beyond destabilization of the embedding matrix in the path of the electron beam. However, for heterogeneous particles/materials in the upper portion of the colloidal size range and larger, there comes a requirement for a three-dimensional orientation within the particle/material. This is especially true when data on the heterogeneity within a colloid system must be assessed by statistical analyses for colloid–colloid associations

and intrasystem gradients. Measurements sufficient to obtain representative data often impose on the analyst a need for large numbers of ultrathin sections (the use of thicker sections not being an option for conventional EM). Detailed analyses of heterogeneous colloid systems in the true particle size range, especially comparative analyses requiring serial sectioning ( $< 50$  nm thick), are possible in theory but not possible in practice because of prohibitive cost (e.g., the cost of analyzing  $10^5$  sections). To minimize the number of sections to be analyzed while achieving the intraparticle orientation necessary to understand what is representative, the analyst makes use of correlative microscopy. This is defined as a strategy for utilizing several different kinds of microscopes and accessory techniques in a multi-method context to analyze a given type of specimen for different kinds of information. Examples wherein a systematic approach to orientation (by means of correlative microscopy) can prove invaluable in reducing the time and cost of analysis include the following:

- Sedimentary materials whose irregular porosity and/or low degree of crystallinity must be quantified or at least assessed.
- Coatings whose degree of patchiness in the coverage of solid surfaces must be assessed.
- Biofilms whose activities under study relate to the disposition of individual colloid species (including biological species) with respect to the interface between colloid system and aquatic milieu.
- Growing flocs whose mechanism of aggregation is sought, in time-series experiments, through morphological correlates.
- Natural associations of colloids whose frequency of occurrence must be quantified for the interpretation of some biogeochemical processes.

A general correlative strategy for microscope analyses is outlined below; detailed considerations have been published in recent reviews.

Descriptions of entire fresh particles in their natural water, by various techniques of light microscopy (LM) including confocal laser scanning microscopy, organized in concert with research goals, should serve as a starting point. This effort can be augmented by LM descriptions of particles (as whole mounts or in thick sections) preserved for purposes of substance-specific staining. The resolution limit of classical LM techniques extends down to  $\sim 0.2 \mu\text{m}$ . As a result of a revolution in LM methodology, however, it has become possible to detect structural features many times smaller than implied by the resolution limit. The main contribution to this advanced

methodology is the use of computers for the digital processing and analysis of images, as is the case for video-enhanced-contrast microscopy. Morphological and microchemical information from LM, on a positional basis, can be related to the high-resolution images of TEM through the intermediary use of many specialized biomedical techniques, one of which is conventional scanning electron microscopy (SEM). SEM provides a higher level of resolution than LM while permitting a varied selection of topographical views (of and through particles) that relate to the entire volume of a colloid system. Like LM, it has a great depth of focus relative to TEM; unlike LM, its capacity to resolve the finest details of ultrastructure can approach that of TEM. Additionally, the latest generation of ESEM instruments (environmental scanning electron microscopy) allows one to obtain topographical views almost as detailed as those provided by SEM, but with (fully or partially) hydrated samples.

When properly oriented (using LM and SEM in sequence) with respect to 'particle volume' and the heterogeneity contained therein, the analyst can then employ a selective sectioning approach to provide the ultrathin (essentially planar) specimens for TEM analyses of the finest details at a practical resolution near 1 nm. As STEM instruments continue to improve in quality, versatility, and convenience, the distinctions between TEM and SEM will become blurred. As the potential of the high-voltage EM (or HVEM) becomes more developed for use with the weakly ordered colloid systems taken from natural waters, the need for ultrathin sections should diminish. An HVEM instrument operated at  $10^3$  keV can achieve the same resolution as a TEM instrument operated at  $10^2$  keV when using sections 20 times the thickness permitted by TEM.

EM accessories and adjunct techniques have become increasingly useful on a routine basis to produce information on compositional differences within a colloid system on a 'per colloid' basis. EDS is readily applied to embedded particles (both sections and films), with greatly improved spatial resolution over the whole mount measures of the past. Conventional STEM-EDS provides qualitative elemental composition analyses for elements of atomic number greater than 10. When standards can be created with realistic matrix properties, good semi-quantitative measures can be made (relative amounts of major elements). Some specialized instruments can detect some elements of  $Z < 10$ , as can a related accessory technology, that of EELS. When precautions are taken to minimize instrument destruction of sample during irradiation, diffraction patterns can be obtained from embedded crystals in the near-nanometer

size range (least dimension), although the smallest crystals tend to provide a pattern useful only for fingerprinting purposes (when applied to samples whose gross chemical composition has been ascertained previously). In addition to selective staining and classical microchemistry, both radioautography and enzyme-site visualization techniques can be adapted from LM applications for use with TEM and STEM. One may also add to the list of analytical adjuncts the experimental tools of immunochemistry and selective extraction. Multimethod approaches to EM preparation, when used judiciously, will allow one to assess various kinds of artifact contributions when a given adjunct technique does not permit the use of a minimally perturbing technique of EM preparation.

## Introduction

Many physical and chemical methods have been described for the measurement of water. However, a universal method has not been found to work for this widely distributed, highly polar compound that occurs in a wide range of concentrations. For example, water forms weak bonds with other polar compounds, can be chemically bound in crystals or simply

trapped in spaces inside them, may evaporate as an azeotrope, and can range from ~100% in biomatrices to trace levels in hydrocarbons. Further, due to the different chemistries possible in a single material, the total amount of water present may not be accessible to measurement. Many methods are not specific for water and other materials with similar physical or chemical properties can bias the measurement, e.g., evaporative methods that measure total volatile material. Many of the common methods cannot measure accurately less than one milligram of water. When greater sensitivity is needed, the coulometric Karl Fischer (KF) method can measure as little as one microgram of water. Some of the methods for water in gases also have similar limits of detection.

Therefore, some knowledge of the nature and range of content of the water in a sample is desirable in choosing a method. Publications of national and international committees and of other organizations that promulgate standard methods for the measurement of water in specific matrices provide widely accepted methods for specific applications. These publications should be consulted early in deciding on an analytical strategy. The methods noted here are described in more general terms.

## Analytical Methods

The choice of a method for the analysis of water in a given sample is dependent on the nature of the sample and the manner in which the water is associated with that sample. The factors that should be considered are listed in **Table 1**.

Both physical and chemical methods are used for the measurement of water. Every chemical method is combined with a physical method that functions as a detector of the product of the chemical reaction. Physical methods usually are independent of chemical reactions and depend only on the absence of signals interfering with the water signal. **Table 2** summarizes the physical methods that have been used for the determination of water and **Table 3** the chemical methods. These tables also list the major detection methods, the limits of detection, and the compounds or groups of compounds that interfere with each type of method.

## Calibration and Standardization

The calibration and standardization of each method are essential for accurate measurements and many

materials are available for calibration. These include liquids containing known amounts of water such as water-saturated 1-octanol ( $39.2 \text{ mg ml}^{-1}$  solution), solids such as oxalic acid  $\cdot 2\text{H}_2\text{O}$  or sodium tartrate  $\cdot 2\text{H}_2\text{O}$ , and gases such as humidity fixed points of binary saturated aqueous solutions or constant-humidity gas generators. Every instrument should be calibrated at the beginning and end of each day with at least three different levels of water that bracket the range of water measurements in the test samples. This procedure will confirm the linearity of the response and the accuracy of the instrument. In addition, a matrix standard, which is similar in composition to the sample, should be used when available to insure that the instrument is responding to the test material in the expected manner. This is particularly important when complex matrices such as pharmaceuticals, foods, plants, paper, oils, or soils are the test materials.

## Sample Considerations

Knowledge of the nature of the sample and the manner in which the water is associated with the sample is essential for the accurate measurement of the water. If the sample is hygroscopic, it may absorb water from the environment and this must be independently measured or a dry box must be used. Occluded water and included water are often incompletely released if the sample is not completely dissolved in a suitable solvent. Some compounds such as copper sulfate bind their water of crystallization so strongly that it is not measured by most methods. Many of the physical methods respond to properties not unique to water (e.g., the OH signal in the infrared (IR) or nuclear magnetic resonance (NMR) methods) or

**Table 1** Factors determining method selection

Factor	Examples
Sensitivity of the method	10 mg per g to 1 $\mu\text{g}$ per g of sample
Type of water	Surface water Water occluded in spaces in crystals Water of crystallization, e.g., water in the oxalic acid crystal structure Azeotropic water, e.g., ethanol/water
Substances that bias the measurement method	Nonaqueous volatile components, e.g., chemicals that evaporate below the boiling point of water Nonaqueous materials to which the detector responds, e.g., hydroxyl compounds that overlap with IR signal for water Nonaqueous materials that interfere with a critical chemical reaction, e.g., ketones and aldehydes that react with the Karl Fischer reagent Water generated or consumed by chemical side reactions, e.g., esterification or amide formation
Type of sample	Gas, liquid, or solid
Sample solubility	Samples must dissolve in chemical assay systems to insure that all the water is available for analysis, e.g., liquids and solids in Karl Fischer reaction

**Table 2** Physical methods for the measurement of water

<i>Method</i>	<i>Detection</i>	<i>Limitations and interferences</i>
Gravimetric (GR)		
Oven drying	Weight loss	Substances volatile $\leq 100^{\circ}\text{C}$ , azeotropes, bound water
Dessication	Weight loss	Bound or occluded water
Thermogravimetric (TGR)	Weight loss	Substances volatile $\leq 100^{\circ}\text{C}$ , azeotropes, bound water
Lyophilization	Weight loss	Bound or occluded water, sublimates
Condensation	Weight of condensate	Substances volatile $\leq 100^{\circ}\text{C}$ , azeotropes, bound water
Distillation	Volume or weight	Substances volatile $\leq 100^{\circ}\text{C}$ , azeotropes, bound water
Chromatography		
Gas (GC)	GC detectors	Column selectivity, azeotropes
Head space	GC detectors	Column selectivity, partition coefficient accuracy, azeotropes
Ion exclusion	UV detector	Requires very dry solvent, chemical reaction not totally specific
Spectroscopic		
Infrared (IR)	Various IR detectors	Water signal overlaps amine and hydroxyl signals, influenced by hydrogen bonding of water, trimer, and dimer forms of water have different signals
NMR	NMR spectrometer	Limited to samples with $> 1\%$ water, exchange of water protons with other protons, nonwater protons
Visible	Spectrophotometer	Requires dry organic polar reagents and is useful for compounds that do not react with the indicator reagent such as those listed in <b>Table 3</b>
Ultraviolet	Spectrophotometer	Requires dry organic polar reagents and is useful for compounds that do not react with the indicator reagent such as those listed in <b>Table 3</b>
Mass spectrometry (MS)	Mass spectrometer	Requires complex calibration, interferences ammonia and atmospheric water
Microwave	Microwave spectrometer	Dependent on the properties of the material, limited range of measurement
Electrical		
Dielectric	AC bridge system	Most materials do not behave ideally, each individual material must be calibrated separately
Conductimetry	Conductivity meter	Requires the presence of a low concentration of a background electrolyte, and that the other components be nonconductive
Coulometry	Coulometer	Requires the quantitative removal of water from sample by an electrochemical reaction
Neutron scattering	Neutron collector	Requires neutron source, nonaqueous hydrogen sources interfere
Differential scanning calorimetry (DSC)	Heat sensor	Requires that the heat of dissociation of the water is compensated by the heat of transition of the sample, useful for determining water in some hydrates
Evolved gas	IR, MS, GC, GR	Substances volatile $\leq 100^{\circ}\text{C}$ , azeotropes, bound water
Density	Densitometer	Requires that only water be extracted into analytical solvent
Refractive index (RI)	RI meter	Requires that only water be extracted into analytical solvent
Water (humidity) sensors		
Thin film polymer/metal oxide	Capacitance or resistance meter	Measures water in gases; range $10^{-3}$ –20% water
Oscillating crystal	Microbalance	Measures water in gases; range $10^{-5}$ –20% water
P <sub>2</sub> O <sub>5</sub> hygrometer	Coulometric	Measures water in gases; range $10^{-5}$ –20% water
Dew/frost-point hygrometer	Thermometer	Measures water in gases; range $10^{-5}$ –90% water

gravimetric evaporative methods that measure all compounds that volatilize at or below  $100^{\circ}\text{C}$ . Thus, the selected method must take into account the properties, composition, and structure of the sample.

### Method Selection

The methods for the measurement of water utilize one of the fundamental physical properties of the water molecule such as a phase change (evaporation) or the absorption of energy (spectroscopy). The

**Table 3** Chemical methods for the measurement of water

Method <sup>a</sup>	Fundamental reaction	Detection	Interferences and limitations
Karl Fischer <sup>b</sup>	$\text{H}_2\text{O} + \text{I}_2 + (\text{RNH})\text{SO}_3\text{CH}_3 + 2\text{RN} \rightarrow (\text{RNH})\text{SO}_4\text{CH}_3 + 2(\text{RNH})\text{I}$	Colorimetric titration, coulometry, or amperometric titration	Substances that react with methanol or iodine, insoluble compounds, range $\geq 1 \mu\text{g}$ water
Acyl halides	$\text{C}_5\text{H}_5\text{NCH}_3\text{COCl} + \text{H}_2\text{O} \rightarrow \text{C}_5\text{H}_5\text{NHCl} + \text{CH}_3\text{COOH}$	Titration with alkali	Range varies from 0.02% to 3% water depending upon the sample
Anhydrides <sup>c</sup>	$(\text{R}^1\text{CO})_2\text{O} + \text{H}_2\text{O} \rightarrow 2\text{R}_2^1\text{COOH}$	Conductimetric, polarimetric, thermometric, or UV	Alkenes, furans, aromatic, ketones, formic acid, aldehydes, amides, and oximes; range 0.2–10% water depending upon the sample
Calcium carbide	$\text{CaC}_2 + \text{H}_2\text{O} \rightarrow \text{C}_2\text{H}_2 + \text{Ca(OH)}_2$	Acid titration	Not always quantitative, range $\geq 1\%$ water depending upon the sample
Hydrides	$\text{CaH}_2 + \text{H}_2\text{O} \rightarrow 2\text{H}_2 + \text{Ca(OH)}_2$	Acid titration or thermometry	Acetone, alcohols, ammonia, and other compounds; range 0.2–90% water depending upon the sample
Magnesium nitride	$\text{Mg}_3\text{N}_2 + 6\text{H}_2\text{O} \rightarrow 3\text{Mg(OH)}_2 + 2\text{NH}_3$	Kjeldahl method for nitrogen	Methanol and compounds that release ammonia, range $\geq 1\%$ water
Lead tetraacetate	$\text{Pb(OOCCH}_3)_4 + \text{H}_2\text{O} \rightarrow \text{PbO}_2 + 4\text{CH}_3\text{COOH}$	Iodine titration	Used for water in acetone, pyridine, and diethylether
Tertiary butyl orthovanadate	$[\text{CH}_3)_3\text{CO}]_3\text{VO} + \text{H}_2\text{O} + \text{NH}_3 \rightarrow \text{NH}_4\text{VO}_3 + 3(\text{CH}_3)_3\text{COH}$	Titration with ammonium iron(II) sulfate	Range $\geq 0.5\%$ water

<sup>a</sup>For maximum accuracy, sensitivity, and precision all of the chemical methods require that the reaction be performed in a closed system or a dry box, that the solvents be dried, and that the samples be completely soluble in the solvent.

<sup>b</sup>RN = pyridine or an alkyl amine.

<sup>c</sup>R<sup>1</sup> = CH<sub>3</sub>(CH<sub>2</sub>)<sub>x</sub>.

accuracy and precision of any given method depend upon the ability of a method using a basic physical principle to detect and distinguish between the compound of interest and other compounds whose properties are similar to the compound of interest (water as in Table 2 or a chemical compound derived there from as in Table 3).

At the outset it is necessary to define two terms used in water measurement, humidity, and moisture. Humidity is defined as a relatively high mass fraction of water or water vapor. Moisture is defined as condensed or diffused liquid. For example, a distillation method measures moisture, i.e., a mixture of compounds (which may include water) that undergoes a phase transition in a specific temperature range.

The physical properties of water that are used for its measurement, e.g., the absorption of wave motion or magnetic energy, or the conduction of electricity, require separation of water from compounds that may interfere with the measurement (Table 2). Usually water is separated by a phase transition from a liquid or solid to a gas. Other methods utilize chemical properties (Table 3) for water determination. Chemical measurements are achieved either by

measuring the water *in situ* or by removing the water from the sample and then quantifying it.

The nature and purity of the sample are also a major consideration. If the sample is primarily a single chemical compound (as opposed to a complex sample like soil or a biological tissue) then many of the methods summarized in Tables 2 and 3 can be utilized to measure the water with a relatively high degree of accuracy. Alternatively, if the material is heterogeneous, the water can be removed from the sample and the amount of sample remaining can be measured gravimetrically, or the water in the moisture that has been removed from the sample can be measured. The water can also be measured directly in the intact sample. The methods that measure the water in intact heterogeneous samples are subject to multiple interferences (see Tables 2 and 3) and are not very sensitive, i.e., they are limited to water amounts that are greater than 0.1%. These methods that measure water in intact insoluble samples (e.g., microwave or IR absorption, or dielectric properties) are frequently used to assess product quality during or after processing and play a very significant role in water measurement. (For applications see Further Reading.)

## Measurement of Water in Liquids and Solids

### Karl Fischer Method

The most widely used method for the measurement of water in liquids and solids is the KF method. The fundamental reaction with water is

(ROH = alcohol, other amines can replace pyridine).

The  $2\text{I}^-$  formed in the second reaction is determined either by visual chemical titration with a reagent such as sodium thiosulfate in the presence of a suitable endpoint indicator or by amperometric, coulometric, or photometric titration methods. The most sensitive KF methods for the measurement of iodine are coulometric. For both the volumetric–amperometric and coulometric methods the endpoint is detected by a pair of platinum electrodes called the indicator electrodes. An electrical potential (100–400 mV) is applied across the electrodes to balance the circuit and the endpoint is reached when the concentration of  $\text{I}_2$  ( $\approx 50 \mu\text{mol l}^{-1}$ ) depolarizes the cathode deflecting a galvanometer. The volumetric method measures the amount of standardized reagent necessary to depolarize the platinum electrodes. The coulometric method utilizes, in addition to the indicator electrodes, a second pair of platinum electrodes (generator electrodes) that electrolytically convert the  $\text{I}^-$  to  $\text{I}_2$ . The current consumed in this process is used to calculate the amount of water using the equation that describes Faraday's laws of electrolysis.

The advantages of the coulometric method are its simplicity of operation, its increased sensitivity, and the fact that it does not require a standardized reagent, such as water saturated 1-octanol, to calculate the water content but only to assess the accuracy of the instrument. The advantage of the volumetric method is that it permits the use of a wider range of very polar solvents as well as nonpolar solvents for dissolving the sample in the titration vessel. Furthermore, the volumetric titration vessel can be heated to enhance the dissolution of slightly soluble samples. Either the volumetric or the coulometric titration instrument can be joined with an oven (evaporation) or a distillation apparatus (azeotropic distillation). In this configuration, the moisture that is volatilized from the sample can be transported to the titrator with a dry gas and the evaporated water measured either coulometrically or volumetrically. The recent

addition of an oven with an autosampler to a coulometric titrator has the added advantage of automated analysis of small amounts of water in insoluble samples with increased sensitivity ( $\geq 50 \mu\text{g}$ ) and with good precision.

### Gravimetric Methods

Gravimetric methods have been used widely because of their apparent simplicity. Their utility is limited by the accuracy of the balance that is used to make measurements. More importantly, these methods measure moisture, of which water may only be one component. If there are no other volatile compounds in the material of interest and the water is not bound, this method is satisfactory but these are two very important caveats.

### Spectroscopic Methods

All spectroscopic methods are based upon the absorption of energy of a specific wavelength, a group of wavelengths, or range of wavelengths. The fundamental process of each of these spectroscopic methods is described under specific headings in this Encyclopedia. Specific wavelengths in the ultraviolet (UV) or visible regions of the spectrum are used for the detection and quantification of light-absorbing compounds that result from the chemical reactions of specific compounds with water (see Table 3). The NMR and mass spectrometry instruments are expensive and complex to operate. The NMR method consists of the magnetic perturbation of molecules caused by the absorption of electromagnetic energy. Two basic types of NMR instruments are used. One is based on the continuous-wave or wide-line method and the other on the pulsed or transient-response method. These methods are limited to compounds that do not exchange OH hydrogen with other exchangeable hydrogen and do not have OH signals that overlap with the water signal. This method is not very sensitive (i.e., water concentrations  $> 1\%$ ). Mass spectrometry consists of electron bombardment of water molecules yielding a spectrum consisting primarily of the peak due to the  $\text{H}^{16}\text{OH}^+$  ion. Usually, the contribution from other ions is negligible. This method can give reliable results from 10 to 0.01% water, when properly calibrated and applied. Microwave analysis is based on the fact that the permittivity of the water is much higher than that of most dry substances. A small amount of water can change the permittivity of the material and can be detected by microwave measuring equipment. This method has a very limited range because the efficiency of these instruments depends on the fluctuation of the density of the sample. However, the sensitivity can be increased

by minimizing the effect of the density fluctuation by the simultaneous measurement of the attenuation and the phase shift of the electromagnetic radiation. This method is capable of distinguishing between bound and free water because the relaxation frequencies for the two forms are significantly different.

The measurement of water by IR methods has become more feasible with the application of laser and Fourier transform infrared (FTIR) technologies. The spectral bands in which water can be determined include both the fundamental IR region ( $4000\text{--}1600\text{ cm}^{-1}$ ) and the near IR region of the combination and overtone absorption bands ( $143\,000\text{--}5000\text{ cm}^{-1}$ ). The IR absorption bands are due to OH stretching, asymmetric OH stretching, and HOH bending. The major problem with this method is that the location of these bands shifts with the matrix and the molecular interaction of water, which forms monomers, dimers, and trimers. Furthermore, the absorption bands of hydroxyl and amine groups of other molecules may overlap with the bands produced by water making quantification difficult or impossible particularly for heterogeneous samples. FTIR is a sensitive method that detects microgram quantities of water when there are no interfering signals. It is applicable to gases, liquids, and solids. However, since absorption bands are prone to shift for each new sample it is necessary to standardize and calibrate the instrument with a matrix standard or by spiking the sample.

## Measurement of Water in Gases

In gases, water measurement capabilities range from parts per billion (ppb) to 100% at temperatures from  $-100^{\circ}\text{C}$  to  $100^{\circ}\text{C}$  and at pressures from 4000 to  $10^7\text{ Pa}$ . A frost-point temperature of  $-100^{\circ}\text{C}$  corresponds to water vapor concentration of 14 ppb ( $14 \times 10^{-7}\%$ ) by volume or 8 ppb ( $8 \times 10^{-7}\%$ ) by weight in air at standard atmospheric pressure. Smaller trace quantities do not appear to have any significant technological, commercial, or scientific importance except in industry where ultrahigh purity of gases are required in the processing of semiconductor and microelectronic devices. The major industrial application for utilizing saturated water vapor is in steam technology.

Five primary technologies are utilized to determine the water vapor content in gases:

1. Dew/frost-point hygrometer – utilizing a chilled mirror surface. The mirror is maintained at the dew-point temperature by automatically controlling the current through a thermoelectric cooler. A  $100\text{-}\Omega$  platinum resistance thermometer is embedded beneath the surface of the mirror to measure the temperature at which dew or frost forms.
2. Coulometric hygrometer – utilizing a thin coating of phosphorous pentoxide ( $\text{P}_2\text{O}_5$ ). Water is completely absorbed by the  $\text{P}_2\text{O}_5$ , forming phosphoric acid, which is electrolyzed to oxygen and hydrogen. The electrolytic current generated is proportional to the amount of water vapor contained within the sample.
3. Electric hygrometer – utilizing a substrate, such as a thin film of polymer or aluminum oxide. Water from a sample is absorbed by the film that causes changes in the electrical properties of the film, such as capacitance or resistance. The change of the electrical quantity is related to the amount of water vapor contained in the gas sample and the amount of water is calculated by use of a calibration curve derived from standards.
4. Oscillating crystal – is a microbalance that utilizes a piezoelectric crystal, such as quartz, pulsed by high-frequency electrical energy that causes it to oscillate. Water from a sample is absorbed on a thin film of polymer or metal oxide deposited on the crystal, causing a change in the oscillating frequency. This change is proportional to the amount of water vapor contained within the sample. This is a gravimetric method.
5. Spectroscopic analyzer – utilizing electromagnetic radiation, such as IR or UV radiation. Water from a sample absorbs the radiation resulting in a decrease of radiation emanating from the gas that is proportional to the amount of water vapor contained within the gas sample.

Differences exist between the capabilities of measurements by the different hygrometers. The spectroscopic analyzer has a limited range of capability ( $10^{-4}\text{--}10^{-7}\%$  water), lacks simplicity of operation, and requires significant maintenance, but it has a fast response time. The oscillating crystal and electrical hygrometers have a broad range of capability ( $10^{-4}\text{--}1\%$ ), oscillating crystal hygrometer, the coulometric hygrometer, and the spectroscopic analyzer have high sensitivity in the range to  $10^{-4}\text{--}10^{-7}\%$  water. The chilled-mirror hygrometer is capable of measuring the dew-point temperature from  $0^{\circ}\text{C}$  to  $90^{\circ}\text{C}$ . With cooling it can measure a broad range of frost-point temperature range from  $0^{\circ}\text{C}$  to  $-90^{\circ}\text{C}$ . The full measurement range of the chilled-mirror hygrometer is  $10^{-5}\%$  to 90% water.

In addition to measurements of the humidity of atmospheric air, which is the most frequent, measurements are also made in such technologically important gases as argon, helium, neon, nitrogen, oxygen, methane, sulfur dioxide, refrigerants, and natural gas.

The above mentioned five primary technologies have been utilized to conduct the measurements for these gases with limited accuracy. The best of the commercial hygrometers have uncertainties  $\sim 1\text{--}2\%$  of the reading. Most hygrometers tend to have uncertainties  $\sim 3\text{--}10\%$  at  $10^{-7}\%$  water levels of concentration.

## Introduction

X-rays constitute the part of the electromagnetic spectrum with wavelengths between  $\sim 0.01$  and  $10\text{ nm}$  ( $0.1\text{--}100\text{ keV}$ ), which is between gamma radiation at the short-wavelength/high-energy side and the vacuum ultraviolet region at the long-wavelength/low-energy side; these boundaries are not clearly defined. Both wavelength units and energy units are used for their identification. With  $hc/\lambda = \text{energy}$ , the conversion between them is  $\lambda\text{ (}\text{\AA}\text{)} = 12.36/E\text{ (keV)}$ .

X-rays were discovered in 1895 by Röntgen (Nobel prize, 1901) when electrons (cathode rays) were decelerated on the walls of a discharge tube. This new type of radiation showed characteristics similar to those of light but, due to limited experimental facilities, Röntgen nor his contemporaries could find evidence for the fundamental properties of this light: polarization, diffraction, reflection, and refraction. Hence, they were described as 'X'-rays (for unknown). In 1896, Perrin was the first to be able to measure the intensity of X-rays by means of an air ionization chamber. In the period 1906–1911, Barkla discovered that X-rays could be polarized and that there was evidence of element-specific absorption edges and emission line series, labeled K, L, M, etc. In 1912, von Laue, Friedrich, and Knipping established the wave character of X-rays by showing that they could be diffracted. The next year, Coolidge introduced the hot filament, high-vacuum X-ray tube, which is still used today. By then, the

experiments of Bragg had shown that the X-ray spectrum emerging from such a device consists of a continuum, on which a specific line spectrum characteristic of the anode material is superimposed. In 1913, Moseley established the relationship between the wavelength of the characteristic lines and the atomic number, thus providing the basis of qualitative and quantitative X-ray spectrochemical analysis. In the same period, Chadwick observed that X-rays can also be produced by bombardment of a material with  $\alpha$ -particles, thus laying the foundation of particle- or ion-induced X-ray emission (PIXE) analysis. Between 1913 and 1923, Siegbahn systematically measured the wavelengths of the X-ray spectrum of the elements. In 1920, Bergengren observed the effect of the chemical state of the absorber on the X-ray absorption spectra of materials and, in 1923, Glocker and Frohnmeyer applied X-ray absorption (XAS) spectrometry for the first time. In 1922, Hadding initiated the use of the X-ray spectra of minerals for chemical analysis. In the period 1923–1932, Hevesy, Coster, Nishina, Glocker, and Schreiber investigated the possibilities of X-ray fluorescence (XRF) spectroscopy as a means for qualitative and quantitative elemental analysis.

The earliest commercially available X-ray spectrometer appeared on the market in 1938. Ten years later, Friedman and Birks built the prototype of the first commercial X-ray secondary emission instrument. Somewhat later, Castaing and Guinier built the first electron probe microanalyzer using a focused electron beam to induce X-ray emission of the elements present in microscopic samples using electron probe X-ray microanalysis (EPXMA). The use of protons in PIXE for chemical analysis was first demonstrated by Sterk in 1964. From the 1960s until the present day, the use of large-particle accelerators (synchrotron rings) has resulted in a dramatic

increase in the variety, scope, and applicability of X-ray-based methods for the characterization and analysis of materials using X-ray fluorescence analysis and related methods.

## Properties of X-Rays

On their passage through matter, X-rays undergo different modes of interaction, reflection, refraction, diffraction (e.g., by slits, gratings, or crystal structures), polarization, elastic and inelastic scattering, photoelectric absorption, and electron–positron pair production (above twice the rest mass energy of the electron; 1.02 MeV, i.e., for very hard X-rays and  $\gamma$ -rays). Diffraction forms the basis of the structural investigation of crystalline materials; it is also used in wavelength dispersive modes of X-ray detection for XRF. The reflective and refractive properties of X-rays are not directly employed in analytical methods but can sometimes improve the analytical qualities of a method, as in the case of total-reflection X-ray fluorescence analysis (TXRF) and in the use of X-ray optics for focusing X-rays. Photoelectric absorption of X-ray photons is employed in many methods such as XRF, XAS, and XPS (X-ray photoelectron spectroscopy, also called electron spectroscopy for chemical analysis, ESCA). Scatter phenomena are usually not employed directly in analytical applications but may be used to influence the polarization of primary X-rays, or to estimate additional properties of materials under investigation (e.g., the thickness and/or mean atomic number of materials).

### Interaction of X-Rays with Matter

A narrow, monochromatic beam of X-rays of energy  $E$  and intensity  $I_0$ , which is transmitted through a foil of thickness  $d$  is attenuated to a value  $I(d)$ . The attenuation is the result of the interaction of the X-ray photons with matter and varies with the foil thickness according to

$$I(d) = I_0 e^{-\mu_L d} = I_0 e^{-\mu \rho d} \quad [1]$$

$\mu_L$  and  $\mu$  are, respectively, the linear and mass absorption coefficients of the material and depend on the photon energy and on the composition of the foil;  $\mu = \mu_L / \rho$  where  $\rho$  is the density of the material. For a complex material consisting of  $n$  elements, each element present with a weight fraction  $w_i$  ( $1 < i < n$ ), the mass absorption coefficients can be approximated as a sum of the atomic components:

$$\mu(E) = \sum_i w_i \mu_i(E) \quad [2]$$

where  $\mu_i$  represents the mass absorption coefficient of the  $i$ th atomic species. In its turn,  $\mu_i$  can be written as

a sum of three contributions:

$$\mu_i(E) = \tau_i(E) + \sigma_i(E) + \pi_i(E) \quad [3]$$

reflecting the three distinct modes through which X-rays interact with matter.  $\tau$ ,  $\sigma$ , and  $\pi$  (usually expressed in  $\text{cm}^2 \text{g}^{-1}$ ), respectively, represent the total cross-section for photoelectric absorption, for scattering, and pair production. Figure 1 shows the variation of the cross-sections as a function of photon energy for lead. Pair production, which only occurs for X-rays with energy above 1.022 MeV, is not discussed further. Overall, in the energy region up to 100 keV the photoelectric effect dominates.

**Photoelectric interaction** In a photoelectric interaction, X-ray photons are absorbed, i.e., their energy is expended imparting kinetic energy to orbital electrons of absorber atoms. The direct measurement of the photoelectrons is used in XPS/ESCA. As the energy of the original photon must be larger than the binding energy of the ejected electron, the photoelectric cross-section  $\tau(E)$  features abrupt discontinuities (called ‘absorption edges’) at photon energies corresponding to those of the various electronic levels in the atom. These edges are denoted with the letters K, L<sub>I</sub>, L<sub>II</sub>, L<sub>III</sub>, M<sub>I</sub>, ..., M<sub>V</sub>, ... and correspond to the ejection of electrons from the  $1s^{1/2}$ ,  $2s^{1/2}$ ,  $2p^{1/2}$ ,  $2p^{3/2}$ ,  $3s^{1/2}$ , ...,  $3d^{5/2}$ , ... orbitals, respectively. As a result of the creation of inner-shell vacancies, the atom is left in an excited state. A relaxation process follows within  $< 10^{-16}$  s involving the transition of an electron of a higher shell (and thus of higher energy) to the shell where the vacancy was created (e.g., from the L<sub>III</sub> to the K level). A schematic overview of some transitions is presented in Figure 2. The excess energy freed during the transition is either emitted as an X-ray photon (a radiative relaxation) or employed in an internal conversion process in which a second electron from a higher shell is ejected from the atom. Such electrons are called Auger electrons (see Figure 3) and are used in Auger emission spectrometry (AES, not to be confused with atomic emission spectroscopy). In the de-excitation there is competition between X-ray (radiative) emission and Auger emission, the first effect being prominent for the high atomic number elements, the latter for low  $Z$ -elements. The relative fraction of both is the radiative and the Auger yield.

Where radiative relaxation takes place, each transition shown in Figure 2 induces the emission of radiation of specific wavelength/energy, characteristic for the atomic species involved. In Figure 2, the terminology adopted by Siegbahn for the characteristic X-ray lines is used, showing that in an iron

**Figure 1** Mass absorption coefficient of lead as a function of energy. The contribution of various interaction modes is indicated. The inserts show details of the variation in the vicinity of absorption edges. 1 barn =  $10^{-28} \text{ m}^2$ .

**Figure 2** Commonly used terminology of energy levels and X-ray lines.

atom, for example, the radiative  $L_{III} \rightarrow K$  transition corresponds to the emission of a characteristic Fe  $K_{\alpha}$  X-ray photon. The IUPAC notation for this line is Fe  $K-L_3$ . Similar to the characteristic X-rays, Auger

electrons feature discrete energy levels, specific for the atomic species they were ejected from. For the case illustrated in **Figure 3A**, the Auger electron energy  $E_{KLM} = (\phi_K - \phi_{L(III)}) - \phi_{M(V)}$ , where  $(\phi_K - \phi_{L(III)})$  is the energy freed when the vacancy in the K shell is filled and  $\phi_{M(V)}$  the energy required to promote the Auger electron from the  $M_V$  level out of the atom.

Inner-shell vacancies can also be a result of interactions with energetic particles (electrons, protons, etc.); thus, emission of characteristic X-rays and of Auger electrons also occurs when matter is irradiated with electron, proton, or heavier ion beams. These effects are employed in various methods for elemental analysis including PIXE mentioned earlier.

**Scattering of X-rays** Two types of photon scattering can be distinguished, depending on whether the scattered photon loses energy during the process: Compton (or inelastic) scattering and Rayleigh (or elastic) scattering. In terms of their total cross-sections ( $\sigma_C$  and  $\sigma_R$ , respectively), this can be expressed as

$$\sigma(E) = \sigma_C(E) + \sigma_R(E) \quad [4]$$

The principle of Compton scattering is shown in **Figure 3B** and involves the interaction of a photon with a weakly bound atomic electron. Depending on the scattering angle  $\theta$ , the final photon energy  $E = h\nu$

**Figure 3** (A) Schematic representation of the photoelectron absorption followed by characteristic photon emission or Auger electron emission. (B) Compton scattering of an X-ray photon by a magnesium atom.

is given by

$$h\nu = \frac{h\nu_0}{1 + (h\nu_0/m_0c^2)(1 - \cos \theta)} \quad [5]$$

where  $h\nu_0$  is the original photon energy,  $c$  the speed of light, and  $m_0$  the electron rest mass. The inelastically scattered photon has a longer wavelength than before the interaction; the energy difference  $h(\nu_0 - \nu)$  being transferred to the electron, which may be ejected from the atom. The original momentum of the electron also influences the energy transfer, an effect known as Doppler broadening of the Compton lines.

In the case of unpolarized radiation, the probability  $P_c(\theta) d\theta$  for a photon to be inelastically scattered between an angle  $\theta$  and  $\theta + d\theta$  is proportional to the Klein–Nishina differential scattering cross-section

$d\sigma_{\text{KN}}/d\Omega$ :

$$\begin{aligned} P(\theta) d\theta &= \frac{2\pi d}{\sigma_C} \frac{d\sigma_{\text{KN}}}{d\Omega} S(x, Z) \sin \theta d\theta \\ &= \frac{\pi r_0^2}{\sigma_C} \left( \frac{h\nu}{h\nu_0} \right)^2 \left( \frac{h\nu_0}{h\nu} + \frac{h\nu}{h\nu_0} - \sin^2 \theta \right) \\ &\quad \times S(x, Z) \sin \theta d\theta \end{aligned} \quad [6]$$

where  $S(x, Z)$  is the incoherent scattering function,  $Z$  the atomic number of the scattering atom, and  $x = \sin(\theta/2)/\lambda$  the momentum transfer parameter. In the case of plane-polarized radiation, the Klein–Nishina differential cross-section also depends on the angle  $\alpha$  the scattered photon makes with the plane of the electrical field vector of the incident photon, measured perpendicular to the original direction of motion of the photon.

The  $\cos^2 \alpha$  factor causes the differential cross-section to be small for small values of  $\alpha$  so that plane-polarized radiation is preferentially scattered out of the plane of polarization:

$$\frac{d\sigma_{\text{KN}}}{d\Omega} = \frac{r_0^2}{2} \left( \frac{h\nu}{h\nu_0} \right)^2 \left( \frac{h\nu_0}{h\nu} + \frac{h\nu}{h\nu_0} - 2 \sin^2 \theta \cos^2 \alpha \right) \quad [7]$$

In the case of Compton scattering, there is no phase relationship between the incident and scattered X-rays; therefore, this type of interaction is often called incoherent scattering. Not all incoherently scattered radiation, however, has been inelastically scattered. In the case of Rayleigh scattering, the energy of the photon remains unchanged and there exists a definite phase relationship between incident and scattered waves; this type of scattering therefore always occurs in a coherent fashion. The intensity of the radiation elastically scattered by an atom is obtained as the sum of contributions of the  $Z$  bound electrons. The interference of these coherent waves is always constructive provided the phase change over an atomic diameter corresponds to less than  $\lambda/2$ , i.e.,  $4\pi r_a x < 1$  where  $r_a$  is the effective atom radius and  $x$  the momentum transfer parameter.

The probability  $P_R(\theta) d\theta$  for Rayleigh scattering of unpolarized radiation within an angle  $\theta$ ,  $\theta + d\theta$  is given by

$$\begin{aligned} P_R(\theta) d\theta &= \frac{2\pi d}{\sigma_R} \frac{d\sigma_R}{d\Omega} \sin \theta d\theta \\ &= \frac{\pi r_0^2}{\sigma_R} (1 + \cos^2 \theta) |F(x, Z)|^2 \sin \theta d\theta \end{aligned} \quad [8]$$

where  $d\sigma/d\Omega_R$  is called the Rayleigh differential cross-section and  $F(x, Z)$  is the atomic form factor:

$$F(x, Z) = 4\pi \int_0^\infty \rho(r) \frac{\sin 2\pi r x}{2\pi r x} r^2 dr \quad [9]$$

with  $\rho(r)$  the radial atomic electron density function and  $r$  the distance from the nucleus.

For plane-polarized radiation, the differential cross-section is given by

$$\frac{d\sigma_r}{d\Omega} = r_0^2 (1 - \sin^2 \theta \cos^2 \alpha |F(x, Z)|^2) \quad [10]$$

Rayleigh scattering occurs mostly at low energies and for high- $Z$  material (see Figure 1), whereas Compton scattering shows a complementary behavior.

## X-Ray Sources

X-rays are emitted on bombardment of matter by sufficiently energetic electrons, protons, or heavier ions and by irradiation of matter with sufficiently energetic electromagnetic radiation (X- or  $\gamma$ -rays). The former type of radiation is termed *bremsstrahlung*, from the German *bremsen* (to brake) and *strahlung* (radiation). Certain radioactive materials are another type of (mostly) weaker X-ray sources. Very intense beams of X-rays are generated in accelerators where elementary particles (electrons, positrons) at relativistic speeds are forced to alter their direction of motion by means of suitable magnetic fields in a storage ring. This type of radiation is also called synchrotron radiation.

## X-Ray Tubes

The most widely applied source of X-rays is the X-ray tube. Electrons, generated by heating tungsten

or other refractive metal filament, are accelerated toward a cooled anode by means of a 10–100 kV potential difference. The anode is usually made from a high- $Z$  metal (Cu, Mo, Rh, Ag, etc.) with good thermal conductivity and mechanical strength. Bremsstrahlung is generated as a result of the sudden deceleration of the energetic electrons entering the anode. The energy distribution of the continuous (white) X-ray spectrum generated is shown in Figure 4. Its overall intensity is proportional to the tube current  $i$ , the square of the accelerating voltage  $V$ , and the atomic number  $Z$  of the anode.

The continuum extends from a shortest wavelength  $\lambda_{\min}$  up to longer wavelengths. The maximum of the distribution is situated near  $\lambda(I_{\max}) \sim 1.5\lambda_{\min}$ . By changing the tube voltage  $V$ ,  $\lambda_{\min}$ , and

$$I(\lambda) \propto \frac{iZ}{\lambda^2} \left( \frac{1}{\lambda_{\min}} - \frac{1}{\lambda} \right) \quad [11]$$

$$\lambda_{\min}(\text{nm}) = \frac{1.2396}{V(\text{kV})} \quad [12]$$

$\lambda(I_{\max})$  can be varied. The high  $\lambda$  cut-off of the spectrum is determined by absorption in the exit window, usually a 5  $\mu\text{m}$  beryllium foil.

Since penetrating electrons in the anode of energy  $E$  higher than the binding energy  $E_0$  also eject core-level electrons from the anode atoms, characteristic lines of the anode material are superimposed on the Bremsstrahlung continuum. The line-to-continuum intensity ratio is a function of atomic number of the

**Figure 4** Effect of the X-ray tube current  $i$  (mA), potential  $V$  (kV), and target atomic number  $Z$  on the output spectrum of an X-ray tube. The dotted line indicates the maximum of the distribution.

anode material and the overvoltage  $E/E_0$ . The relative importance of the continuum and line contributions to the overall X-ray intensity delivered is strongly dependent on the anode materials.

### Types of X-Ray Tubes

There are several types of X-ray tubes but since Coolidge introduced the (side-window) X-ray tube in 1913, a variety of modifications to his basic design have been proposed. The ideal X-ray tube produces sufficient photon flux over a wide spectral range with a stability better than 0.1%. Via a switchable tube potential (usually in the 10–100 kV range), it is possible to optimize the shape of the tube spectrum for the intended application.

The X-ray tube is characterized by the anode element, its input power (0.2–5 kW for conventional high-power tubes), the anode–cathode voltage (10–100 kV), the tube current (0.1–100 mA), and the exit window thickness and composition. Other important features are the angle of incidence of the electrons with the anode and the take-off angle of the X-rays. The radiation output power is of the order of 1% of the input power and (in the side-window tube (SWT)) roughly varies with  $I/t^2$ ,  $t$  being the anode-window distance. In the SWT, the reduction of this distance is limited by the increase in electron bombardment and heating of the window with decreasing  $t$ . An arrangement where this is avoided (permitting smaller  $t$  values) is the end-window tube (EWT). Whereas in the SWT the window and anode are at ground potential, in the EWT the filament and window are grounded while the anode is at a positive potential. In the EWT, electrons are directed to the anode by means of suitable electron optics. Because of the smaller anode-window distances and the fact that the tube voltage is applied between anode and window, EWT tubes voltages are limited to  $\leq 60$  kV.

A configuration in which  $t$  is reduced to zero is called the target transmission tube (TTT). The anode material is evaporated directly on the beryllium window. The anode is irradiated from the back while a significant part of the bremsstrahlung escapes from the front and exits the tube. This geometry requires a much lower input power (200 W compared with 3 kW for the conventional EWT) and, as a result, does not normally require cooling with water.

In order to remove the limitation in the input power caused by excessive heating/melting of the anode in the SWT geometry, the rotating anode tube was developed. By employing a cylindrical anode head that rotates rapidly through the electron beam, an output power gain by a factor of 5–10 relative to

conventional designs can be achieved. The anode head must be perfectly aligned so that the spot on the anode surface where the X-rays originate from is a fixed point in space. The anode head itself is equipped with an integrated high-power cooling system.

The TTT and rotating anode tubes are relatively recent developments for which the application field is still growing; the most popular type of X-ray tube is still the SWT.

Nowadays small, compact tubes are also popular for various applications. For many of these, the brilliance is the vital parameter rather than the total delivered X-ray intensity. Thus, low-power tubes are interesting tube configurations for  $\mu$ -XRF. For a side looking, microfocus tube with 50–100  $\mu$ m spot size, the brilliance is comparable to the high power tubes, although the total power does not exceed more than a few watts.

### Radioactive Sources

X-rays of discrete energy are also generated as a result of various types of radioactive decay processes. In such processes harder radiation ( $\gamma$ -rays) is usually produced as well. Table 1 gives an overview of radioisotopes most commonly used as sources of X-rays, together with some of their characteristics.

Radioactive sources have the advantage that they produce monochromatic radiation, are very compact and easy to use, and straightforwardly produced. As a consequence, they are frequently used in portable (and/or hand-held) XRF spectrometers which are used, for example, for *in situ* analysis of soil, waste materials, etc. In other applications, the absorption or

scattering of the primary X-rays is employed, e.g., to estimate the mass or mean atomic number of the material irradiated. A disadvantage of radioactive sources is the limited lifetime and relatively low flux of primary radiation.

### Synchrotron Sources

Synchrotron radiation produced in storage rings are now employed on a routine basis as radiation sources for X-rays for various X-ray applications exploiting the very high intensity and the possibility to obtain monochromatic radiation on a microscopic spot.

## Detection of X-Rays

X-rays cause ionization in gases, liquids, and solids, thereby altering the electrical properties of these materials. Gas ionization is the basis of gas-filled detectors such as ionization chambers, Geiger-Müller counters and proportional counters are used in conjunction with X-ray dispersion. The ionization of silicon atoms in the solid state forms the basis of the lithium-drifted (Si(Li)) semiconductor detector, making energy-dispersive detection of X-rays possible.

The fact that photographic materials are sensitive to X-rays allows for the photographic recording of X-ray intensities and spectra and is the basis of film-badge dosimetry. The fact that X-rays can induce visible and/or ultraviolet luminescence in certain materials is used in scintillation counters and fluorescent screens.

### Gas-Filled Detectors: Ionization Chambers, Proportional Counters, and Geiger Counters

The principle behind these radiation detectors is the photoionization of gas molecules and/or atoms followed by the separation and collection of the resulting ions by means of an electric field. The differences between the various types can be explained by means of Figure 5, which shows a cylindrical conducting chamber containing an axial anode wire insulated from the chamber walls. The chamber is filled with an inert gas (e.g., argon or helium) at a pressure of 1 atm or less; the anode is at a positive potential  $V$  relative to the chamber walls. When radiation passes through the chamber, ion-electron pairs are formed due to photoionization of the gas atoms/molecules. Even at small potential differences (e.g., 10 V), all electrons produced in this way are immediately accelerated toward the anode, resulting in a current pulse in the external circuit. For a range of potentials (the ionization chamber region, region B in Figure 5) the number of ion pairs  $n$  is independent of the potential  $V$ , although this number is proportional to the energy

**Figure 5** (A) Gas-filled counter with associated electronics. (B) Number of ion pairs  $n$  collected at central electrode as a function of voltage ( $V$ ) for X-ray photons of low (curve 1) and high energy (curve 2). Regions A–F are described in the text.

of the incident photon. Ionization chambers are employed to measure the overall intensity of X-ray radiation and are often employed for normalizing signals collected using more sophisticated detectors.

Above region B, an increase in potential difference also causes an increase in  $n$  as a result of gas multiplication or gas amplification. This phenomenon occurs when the electrons produced by photoionization acquire sufficient energy to produce additional ionizations before they reach the anode wire. As a result,  $n$  increases exponentially with  $V$ , each photoelectron producing an avalanche of secondary electrons. Region C, in which individual electron avalanches are not affected by the presence of others, is called the 'proportional counter' region. Although amplified by a factor  $10^2$ – $10^6$ , the detected signal is still proportional to the photon energy. Proportional counters therefore can be used for energy measurements and to count single events. A maximum count rate of  $\sim 2 \times 10^6$  counts  $s^{-1}$  can be accommodated. Proportional counters are mainly used for detecting soft X-rays ( $\lambda > 0.2$  nm;  $E < 6$  keV). Several types exist, depending on wavelength range of the radiation that needs to be measured. At higher voltages, the number of electron avalanches becomes so large that the remaining positive space charge (formed by the slower moving ions) of one avalanche inhibits the development of the next. As a result, in region D, only a limited proportionality is retained.

Finally, in the Geiger-Müller counter regime (region E), the collected signal becomes independent

of the energy of the original photon. At even higher voltages (region F), the discharge tends to propagate itself indefinitely. Geiger counters are employed for counting (relatively low doses) of radiation ( $<2000$  counts  $s^{-1}$ ); they are usually filled with an argon-ethanol mixture and are operated at 800–1000 V. Alcohol serves to quench discharges in the chamber resulting from the bombardment of the chamber walls by  $Ar^+$  ions.

The energy resolution of the proportional counter is determined by the statistical fluctuations of the number of ion–electron pairs generated by a photon of specific energy. Full-width at half-maximum (FWHM) of the distribution determines the resolution of the detector, which is of the order of 900 eV for a proportional counter. For this reason in X-ray spectrometers this type of detector is always used in conjunction with a dispersive crystal or equivalent.

### Scintillation Counters

This type of detector is only efficient in the hard X-ray range ( $E > 6$  keV,  $\lambda < 0.2$  nm). The scintillation counter consists of a Tl-doped NaI scintillator crystal affixed to the end of a photomultiplier tube. X-ray photons with energy  $E = h\nu$  eject an outer electron from an iodide ion (this process requires  $\sim 30$  eV), thereby transferring most of their energy to the photoelectron. The latter dissipates its energy into the crystal by promoting valence band electrons to an excited state 3 eV above ground level. Upon de-excitation, these electrons emit a 3 eV (410 nm) photon. The intensity of the emitted light pulses is proportional to the number of electrons  $n$  excited by the original X-ray. The NaI (Tl) crystal in which these phenomena occur is aluminized on the outside to reflect the scintillation light toward the photomultiplier tube. In the photomultiplier, the light that strikes the photocathode releases a few photoelectrons. These electrons are then accelerated between the cathode and the first dynode, producing a higher number of electrons as they strike it. In a photomultiplier tube, this process can be repeated up to 10 times until the avalanche of electrons reaches the collector anode, at which the resulting electron current can be measured. Depending on the voltages applied between successive dynodes, an amplification factor of the order of  $10^6$  can be achieved. The amplitude of the final current pulse is proportional to the light intensity entering the tube and thus to the energy of the X-ray photon that originally entered the scintillator crystal.

### Wavelength Dispersion of X-Rays

In view of their complementary sensitivity characteristics, proportional and scintillation counters are

often used in tandem. In such an arrangement, X-ray photons first enter the proportional counter through one window. Those with low energy ( $E < 6$  keV) will mostly be absorbed in the counter gas and detected accordingly; the harder X-rays ( $E > 6$  keV) leave the ionization chamber through a second window to enter the scintillation crystal.

The energy resolution of both detectors is insufficient to allow them to be used directly in X-ray spectrometers. Rather, they are most often used in conjunction with a monochromator so that only photons within a well-defined energy/wavelength band can enter the detector. This monochromatization can be done either by means of dispersive crystals or by means of multilayer systems.

When a parallel monochromatic beam of wavelength  $\lambda$  impinges on a crystal (or multilayer) under an angle  $\theta$ , the photons will be scattered by the atoms in the material. Only in certain directions, in which the path difference between two rays is equal to an integral number of wavelengths ( $n\lambda$ ), constructive interference between the scattered rays occur. The angles  $\theta$  for which this diffraction phenomenon occurs for a given wavelength  $\lambda$  and crystal spacing  $d$  are given by Bragg's law:

$$n\lambda = 2d \sin \theta \quad [13]$$

For  $n=1$ , the path difference between two rays is only one wavelength and the diffraction is said to be of the first order. Second order corresponds to  $n=2$ , etc. By selecting a certain value of  $\theta$  from the diffraction pattern of an incident polychromatic beam, a specific wavelength  $\lambda$  can be selected with a resolution:

$$\frac{d\theta}{d\lambda} = \frac{n}{2d \cos \theta} \quad [14]$$

Depending on the energy/wavelength range the dispersive element operates in, various types of crystals and orientations ( $d$ -spacings) are employed. Table 2 lists a number of currently available natural and synthetic crystals and multilayer systems; the elements whose characteristic lines fall within the operating region of each dispersive element are also indicated. Multilayer systems, with their  $d$ -spacings of the order of 2–12 nm (i.e., much larger than possible in crystals), are used for dispersion of very low energy X-rays ( $0.2 < E < 1.2$  keV;  $1 < \lambda < 6$  nm). In general, for crystal monochromatization, the energy bandwidth of the resulting monochromatic beam is of the order of 1%.

As an alternative to the use of planar crystals and multilayers, in a number of X-ray spectrometers (especially those employing synchrotron radiation or

### Solid-State Detectors

Solid-state energy-dispersive detectors are based on the simple semiconductor diode structure made from, for example, lithium-drifted silicon (Si(Li)) detector or high-purity germanium (HPGe detector). A Si(Li) detector consists of a single-crystalline disk of semiconductor grade silicon consisting of a compensated intrinsic (i-type) region sandwiched between p- and n-type regions, thus forming a p–i–n type diode structure. The central area is made (quasi)intrinsic by diffusing ('drifting') lithium into the p-type silicon to compensate for impurities and dopants present in the crystal. As a result, the Si(Li) crystal features a very low concentration of free charge carriers. The thin p-type layer (typically 0.3  $\mu\text{m}$ ) on the surface of the crystal does not contribute to the detection process and is called the 'dead layer'. Gold film electrodes ( $\sim 20$  nm thick) are evaporated onto the faces of the silicon wafer between which a reverse bias voltage can be applied, creating an active depletion area. Under such

conditions and in the absence of a radiation field the only current flowing between the electrodes is due to thermally generated charge carriers. To minimize this dark current, Si(Li) detectors are operated at liquid nitrogen ( $\text{LN}_2$ ) temperatures (77 K) in a vacuum cryostat at all times. The cooling reduces the noise and ensures optimal energy resolution. It also minimizes diffusion of the highly mobile lithium under the influence of the applied electrical field.

X-ray photons can enter the cryostat and reach the Si(Li) crystal through a thin beryllium window of typically 5–10  $\mu\text{m}$  thickness. The vacuum enclosure protects the detector from surface contamination and moisture condensation (at  $\text{LN}_2$  temperatures), light and scattered electrons (in electron microprobes). For measuring very low energy/long-wavelength X-rays, the beryllium window can be replaced by ultrathin diamond or aluminum coated polyimide windows or (in vacuum instruments) removed completely.

When an X-ray photon enters the active volume of the detector, its energy is transferred to a photoelectron, which in its turn expends its energy by producing electron–hole pairs in the semiconducting silicon crystal; this requires on average 3.76 eV per electron–hole pair. The energy associated with the inner-shell vacancy created by the photoelectric absorption is also absorbed in the crystal, either via the emission by the ionized atom of Auger electrons or low-energy X-rays that are reabsorbed. The total number of electron–hole pairs created is proportional to the energy of the original photons. These free charge carriers are collected by the applied field as a charge pulse that is integrated and amplified to a voltage pulse that can be digitized and stored in a multichannel pulse height analyzer or computer memory, thus collecting the energy distribution of the individually detected photons. Details on the exact functioning of this type of detectors can be found elsewhere. Because of its high-energy resolution (typically  $\sim 150$  eV FWHM for Fe  $K_\alpha$ ), its small size, and high efficiency over a wide spectral region, this type of detector is very useful for the detection of fluorescent X-rays in the 1–40 keV energy range in various types of applications (see below).

### X-Ray Analysis

There are several ways in which the analytical methods that employ X-rays can be categorized. One can make a distinction between techniques that use X-rays to excite sample atoms (as in the case of XPS) and methods that employ the information contained in the energy and number of X-rays emitted by

a material under investigation. In the latter case, the emission of the X-rays can be induced by X-rays themselves (as in the case of XRF and XRD) or by employing beams of charged particles (as in the case of EPXMA or PIXE).

Another subdivision can be made on the basis of the type of information the method provides: structural, elemental, or chemical. Moreover, the information can be derived from a fairly large sample volume, representative of the whole of the material (bulk analysis), or originate from a well-defined (and microscopically small) location on the sample surface (microanalysis). Additionally, the information obtained by an X-ray method may either originate from the topmost layer (analysis of the surface) or emerge from greater depths. For many methods such as XRD, XRF, XPS, AES, the use of synchrotron rings as powerful X-ray sources has prompted the development and maturation of microscopic equivalents.

A short description of each of the most important X-ray techniques will now be given. It is not the intention to provide the reader with a comprehensive overview of all analytical methods that employ X-rays in one form or another, but rather to present a concise discussion of the main points of the most important techniques. Most of these techniques are more exhaustively described in other entries of this work.

### X-Ray Diffraction

Diffraction of X-rays is the basic technique for obtaining information on the atomic structure of crystalline solids and is one of the key standard laboratory techniques. XRD is based on the interference of X-ray waves elastically scattered by a series of atoms orientated along a particular direction in a crystal characterized by a vector  $\mathbf{A}_b$ . The waves scattered by two atoms  $a$  and  $b$  interfere constructively with each other when the path difference PQR is equal to an integer number of wavelengths:  $\text{PQR} = h\lambda$ . This condition is valid for orientations  $\mathbf{K}$  of the scattered waves which satisfy the Laue condition:

$$(\mathbf{K}_l - \mathbf{K}_0) \cdot \mathbf{A}_b = h \quad [15]$$

where  $\mathbf{K}_0$  and  $\mathbf{K}_l$  are the wave vectors of the original and scattered waves. Therefore, by measuring the diffracted intensity as a function of all possible orientations  $\mathbf{K}_l$  relative to  $\mathbf{K}_0$ , data on all possible orientations  $\mathbf{A}_b$  of series of atoms in the crystal can be obtained. Maxima in the diffracted intensity (called reflexes) obtained from a three-dimensional crystal correspond to orientations of  $\mathbf{K}_l$  relative to  $\mathbf{K}_0$  which

fulfill three of the above conditions simultaneously (atoms orientated along directions  $\mathbf{A}_b, \mathbf{A}_k, \mathbf{A}_l$ ). The integer numbers ( $h\ k\ l$ ) are called the Miller indices of the reflex. Since the scattered intensity is a function of the number of electrons around each atomic nucleus, information on which atoms constitute a unit cell of the crystal is also contained in the diffracted intensities. In a single-crystal diffractometer, monochromatic radiation is employed and the crystal and detector system are mounted on goniometer arms, permitting the diffracted intensity along all orientations of  $\mathbf{K}_l$  relative to  $\mathbf{K}_0$  to be accurately measured. More simple setups are appropriate for determining the interplanar distances of polycrystalline or powdered materials (Debye–Scherrer recording).

For laboratory-scale X-ray diffraction, X-ray tubes with copper up to molybdenum and silver anodes are typically employed. By making use of the high-intensity and tunable character of synchrotron radiation, for single-crystal diffraction of more ‘difficult’ systems (very small crystals, weakly scattering systems, radiation-sensitive materials, crystals of very large/complex molecules (proteins, DNA fragments), materials under very high pressure and/or temperature), dramatic improvements relative to the laboratory-based variants have been achieved. Using the related techniques of SAXS and WAXS (small- and wide-angle scattering, respectively), the monitoring of structural changes in materials that are dependent on time, temperature, and/or pressure has also become possible.

### X-Ray Absorption Spectroscopy

As described earlier, in the region 1–40 keV, the photoelectric cross-section  $\tau(E)$  is characterized by discontinuities at the binding energies  $E_b$  of the core level electrons, called absorption edges. Between these jumps, for isolated atoms,  $\log \tau$  versus  $\log E$  curves are nearly straight lines. In condensed matter, however, oscillations on the absorption profiles can be observed close to absorption edges. These features are called the X-ray absorption fine structure (XAFS).

The region from 0 to 40 eV above the actual edge is called the XANES (X-ray absorption near-edge structure) or NEXAFS (near-edge XAFS) region; above 40 eV, the EXAFS (extended XAFS) region commences. Also, pre-edge features may be observed. The fine structure is caused by the interference of the outgoing photoelectric wave front with the waves backscattered from neighboring atoms. For a particular chemical environment of the central atom and for a given photoelectron energy  $E$ , the amplitude of the outgoing photoelectric waves is amplified

(constructive interference) or damped (destructive interference), resulting, respectively, in higher or lower values of  $\tau(E)$  relative to the isolated atom case. From the fine structure, the interatomic distances and coordination numbers around the absorbing atom can be determined. Since the absorption fine structure is caused by the immediate chemical environment of the atomic species involved, the material under study need not show a periodic repetition of this structure in order for the XAFS to be observed. As such, XAS is a very important structural investigation method for studying noncrystalline materials.

The direct method involves measuring the intensity of a highly monochromatic beam of radiation ( $\Delta E/E \leq 10^{-4}$ ) before and after passing through the material under study. From the ratio  $I/I_0$  ( $I_0$  = original intensity,  $I$  = transmitted intensity), the absorption coefficient of the material  $\mu(E)$  at that energy can be calculated (see eqn [1]). The energy of the beam can be continuously varied by changing the Bragg angle  $\theta$  of the double-crystal monochromator. Because of the requirement for such a highly monoenergetic beam, XAS measurements are almost exclusively performed with synchrotron X-ray sources. Since the direct method is confined to samples of limited thickness containing appreciable amounts of the atomic species under study ( $>1\%$ ), for thicker samples (or samples with a lower analyte concentration), instead of measuring the photoelectric absorption directly, the resulting production of fluorescent X-rays is measured. The latter method is known as fluorescent XAS and usually employs solid-state detectors. The two methods are functionally equivalent. Another method involves the measurement of the electron yield. An important variant of the method is SEXAFS (surface EXAFS), in which the photon beam impinges on the sample under grazing incidence, thereby only probing the top few nanometers or less of the sample surface. Applications of XAS are found in the field of metal catalyst research where the chemical environment and oxidation state of the catalytically active metal atoms can be probed, in the geosciences, in electrochemistry, and in materials analysis, where SEXAFS in particular can provide chemical information on the surface of materials as a function of depth.

### X-Ray Photoelectron Spectrometry

Photoelectron spectrometry is a surface analysis technique based on the detection of photoelectrons emitted from a solid sample upon irradiation with a UV (ultraviolet) discharge lamp, an X-ray tube, or a synchrotron source. By means of an electron

analyzer, the energy spectrum of the emitted photoelectrons is recorded. In the XPS spectra, at certain energies  $E_i$ , peaks can be observed, called core electron lines, which correspond to the binding energy levels  $E_{b,i}$  (relative to the Fermi level) of the emitted photoelectrons in the solid under investigation:

$$E_{b,i} = h\nu - E_i - \phi \quad [16]$$

where  $h\nu$  is the energy of the exciting radiation and  $\phi$  the work function of the spectrometer (usually an empirically determined constant). Next to the core electron lines, other bands of lower intensity (close to zero binding energy) are visible which reflect the distribution of electronic states in the valence band of the material. The photoelectrons ejected from the atom in the solid have different kinetic energies  $E_i$  according to the electronic level and type of atom they originate from. XPS therefore permits an elemental analysis of the material under study. All elements except hydrogen can be detected. Furthermore, since the kinetic energy of the photoelectrons also depends on the chemical environment of the ionized atom, the  $E_i$  values shift to lower or higher values as the electronic charge of the atom increases or decreases. This 'chemical shift' allows elemental data about a material to be complemented with chemical information. This phenomenon is also observed in XAS studies.

In laboratory setups, aluminum or magnesium anode X-ray tubes are usually used; the radiation is often monochromatized by means of, e.g., a quartz crystal. In most spectrometers a hemispherical analyzer equipped with electrostatic lenses for collection, acceleration, and focusing of photoelectrons is used; a channeltron or channel plate serves to amplify the primary signal. Although the penetration depth of, e.g., Al  $K_\alpha$  photons is relatively large in solids (typically a few micrometers), the analyzed photoelectrons (having kinetic energies in the 0–1500 eV range) only come from the top 0–10 nm of the material. As a result, XPS is very useful for investigating the extreme surface of materials. XPS detection limits are found at the level of  $10^{12}$ – $10^{13}$  atoms on the surface, corresponding to a relative detection power of 0.01–0.1  $\mu\text{g per g}$  relative to the bulk of the material. XPS experiments must therefore be conducted in an ultrahigh vacuum chamber ( $<10^{-9}$  Torr). A common accessory in the XPS chamber itself is an ion gun for depth profiling purposes. By rastering an area of the surface with a beam of heavy ions (e.g.,  $\text{Ar}^+$ ), thereby gradually removing layer after layer of the surface of the material, XPS spectra of layers of increasing depth with respect to the original sample surface can be recorded. As well as such depth

information, laterally resolved information can also be obtained by using a primary X-ray beam that is focused to a spot 5–20  $\mu\text{m}$  in diameter (small-spot XPS) or by collecting photoelectrons from a microscopically small area on the surface (small-area XPS). In the area of micro-XPS, for soft X-ray excitation, a few types of laboratory-scale instruments are available; for higher energies, the use of synchrotron radiation sources is more appropriate. The tunability, polarization, and brightness of synchrotron light are major advantages in this respect, making it possible, e.g., to optimize the sensitivity for a particular element or to fine-tune the escape depth of the photoelectrons, to perform constant initial and final state experiments, to study the symmetry of electron states at the surface, or to achieve very small spots.

Applications of XPS are found in the broad domain of materials science, involving quantitative surface analysis and stoichiometry determinations, the study of layer growth phenomena, the determination of the oxidation state and the chemical environment of elements, and the investigation of interface structures and compositions.

### X-Ray Fluorescence Analysis

Together with XRD, XRF analysis is one of the most widely applied analytical techniques based on X-rays. The method is aimed at obtaining qualitative and quantitative information on the composition of materials on the basis of the energy and intensity distribution of the characteristic radiation emitted by this material when irradiated with an X-ray beam.

Requiring only relatively simple equipment, XRF spectroscopy is a powerful and convenient nondestructive multielement technique for bulk analysis of a variety of materials that features detection limits in the  $\mu\text{g per kg}$  range for conventional spectrometer types. By employing special excitation conditions (see below), sub- $\mu\text{g per g}$  detection limits can be achieved for most elements heavier than sodium.

Traditionally, for conventional bulk-analysis XRF, a distinction is made between wavelength-dispersive (WD) and energy-dispersive (ED) XRF. Associated primarily with the ED method of detection, several variants of the method exist which either employ alternative excitation forms and/or geometries, use different ways of inducing the emission of characteristic radiation, or constitute a microanalytical version of the bulk technique.

### Wavelength-Dispersive X-Ray Fluorescence

In WD-XRF, an essentially sequential way of collecting the spectrum of characteristic radiation

emerging from the sample is employed. Before reaching the detector, the fluorescent radiation impinges on a suitable monochromator crystal so that only photons of a specific wavelength are diffracted toward the detector. The latter is usually a scintillation counter, optionally preceded by a proportional counter. By rotating the monochromator crystal, the wavelength of the photons entering the detector can be varied and a WD-XRF spectrum recorded. The most important advantage is the wavelength resolution, making accurate and interference-free quantitative analysis possible. Because of the intensity loss that occurs at the monochromatization step, WD-XRF spectrometers are equipped with high-power X-ray tubes. In view of the sequential nature of the data collection process, WD-XRF analysis is well suited for routine analyses (e.g., in industrial quality control processes), whereas ED-XRF is more appropriate for exploratory types of analysis. There also exist parallel variants of WD-XRF spectrometers in which an array of detectors is employed, each measuring the fluorescent intensity at a particular wavelength.

### Energy-Dispersive X-Ray Fluorescence

An ED-XRF spectrometer essentially consists of an X-ray source, a sample holder, and an Si(Li) detector orientated at  $90^\circ$  to the primary radiation. All fluorescent radiation emitted by the sample may be collected in parallel, i.e., without sequential scanning of the energy or wavelength scale. As no significant losses of radiation occur between the sample and the detector, this type of detector is ideally suited for measuring relatively low doses of radiation ( $<10^4 \text{ counts s}^{-1}$ ). An important disadvantage is the relatively low resolving power of the solid-state detectors (typically 120–180 eV at 5.9 keV). This results in considerable peak overlap in ED-XRF spectra, making a reliable quantitative processing of the raw data not straightforward. By employing suitable data evaluation software (fitting of experimental spectra to mathematical models), this disadvantage can almost completely be eliminated.

Because the mechanical requirements of the ED detection geometry are moderate in comparison to the WD equivalent, in the more recently developed analogs or variants of the XRF method solid-state detectors are almost exclusively employed. Such related methods are electron probe X-ray microanalysis (EPXMA) and (microscopic) proton-induced X-ray emission ( $\mu\text{-PIXE}$ ). It should be noted, however, that many EPXMA instruments are also equipped with WD detectors (e.g., for low-Z element analysis). Important variants of the conventional XRF technique that have achieved

considerable success in recent years are TXRF and micro-XRF, using laboratory or synchrotron X-ray sources.

### Electron- and Proton-Induced X-Ray Emission

As described earlier, X-rays can be used to create inner-shell vacancies in sample atoms, but charged particles (in practice, electrons in the 5–100 keV range and protons in the 2–3 MeV range) can also be employed. EPXMA can be performed in most (scanning) electron microscopes equipped with an Si(Li) detector, or in electron microprobe analyzers featuring an Si(Li) detector and one or more WD detection systems. If the electron beam is slowly moved from spot to spot on the sample, while at every point the emerging element-specific radiation is detected, elemental maps can be recorded. Because of the more intense bremsstrahlung, detection limits of EPXMA are in the range 0.1–1%.

If protons are used instead of electrons, a much higher sensitivity can be achieved ( $\mu\text{g per g}$  level for elements lighter than calcium). The PIXE method was originally employed as a bulk analytical method (macro-PIXE) and is performed in a dedicated measuring chamber, installed at a particle accelerator (Van der Graaf or cyclotron); since proton beams can be generated with much higher brilliance (i.e., particle density in the beam) than that of photon beams produced by X-ray tubes, macro-PIXE is ideally suited for analyzing very small amounts of material. More recently, the microscopic variant ( $\mu\text{-PIXE}$ ) has achieved considerable success.  $\mu\text{-PIXE}$  employs a focused proton beam of (sub)-micrometer dimensions for recording maps of elemental species in materials of different kinds.

### Micro X-Ray Fluorescence

$\mu\text{-PIXE}$  and EPXMA have the disadvantage that considerable energy deposition takes place in the sample during irradiation. Another disadvantage is the limited sensitivity of both methods for elements heavier than calcium. Both of these limitations can be overcome by employing a focused beam of X-ray photons instead of charged particles. As X-ray tubes produce a widely divergent cone of primary radiation, in the past such microbeams were not realizable in practice. Recent breakthroughs in X-ray optics and the increasing availability of synchrotron sources provide X-ray beams of sufficient intensity and of micrometer-size diameters can be generated and the number of application fields in which micro-XRF is used is increasing (geosciences, environmental analysis, materials characterization, archeometry).

### Total Reflection of X-Rays

One of the optical properties used in X-ray analysis is total reflection of X-rays at an optically flat surface. This phenomenon occurs when photons impinge on a surface below the critical angle  $\theta_c$  of total reflection. Defined in practical units  $\theta_c$  (in minutes of arc) can be expressed as a function of atomic number  $Z$ :

$$\theta_c = 28.8 \times \frac{1}{E} \sqrt{\frac{Z\rho}{A}} \quad [17]$$

where  $\rho$  is the density ( $\text{g cm}^{-3}$ ) and  $A$  is atomic mass. For X-rays of 10 keV on silicon,  $\theta_c$  is  $\sim 3$  mrad or  $0.2^\circ$ . Total reflection of X-rays is of interest as the X-rays only penetrate very shallowly into the reflector surface. This effect can be employed advantageously in TXRF. The method is able to detect extremely small concentrations of contaminants at the surface of pure materials such as semiconductors. For performing very sensitive multielement analysis of solutions, a microvolume of the solution is pipetted onto an optically flat sample support (e.g., a quartz disk) and allowed to dry. TXRF absolute detection limits are in the 5–50 pg range (without preconcentration) for analysis of trace elements in rain water.

### Introduction

X-rays are characterized by the following features: they are invisible; propagate in straight lines with the velocity of light (in vacuum:  $3 \times 10^8 \text{ m s}^{-1}$ ); unaffected by electric and magnetic fields; differentially absorbed in passing through matter of varying composition, density, or thickness; reflected, diffracted, refracted and polarized; capable of ionizing gases; capable of blackening a photographic plate; capable of producing biological reactions, e.g., to damage or kill living cells and to produce genetic mutations; and able to liberate photoelectrons and recoil electrons. This article describes the interaction of X-rays with matter and provides basic information about the diagnostic use of X-rays, tomography, computed tomography, and nondestructive testing. Qualitative

and quantitative measurements based on the absorption of X-rays are discussed and a brief review of selected applications of X-ray absorption techniques is also given.

### Interaction with Matter

Interactions of photons (including both X-rays and  $\gamma$ -radiation) with matter may be classified according to (a) the kind of target, such as electrons, atoms or nuclei, with which the photons interact, and (b) the type of event, such as absorption, scattering or pair production, that takes place. Possible interactions are summarized in Table 1, where  $\tau$  is the total photoelectric absorption cross-section per atom,  $\sigma_R$  and  $\sigma_C$  are the Rayleigh and Compton collision cross-sections, respectively, and  $K$  is the cross-section for pair production. The sum of all these cross-sections, normalized to a per atom basis, is the probability  $\sigma_{\text{tot}}$  that the incident photon will have an interaction of some kind while passing through a very thin absorber that contains one atom per unit of area normal to the path of the

**Table 1** Classification of photon interactions

Type of interaction	Absorption	Scattering		
		Elastic (coherent)	Inelastic (incoherent)	Multiphoton effects
Interactions with atomic electrons	Photoelectric effect $\tau \propto Z^4$ (low energy) $\tau \propto Z^5$ (high energy)	Rayleigh scattering $\sigma_R \propto Z^2$	Compton scattering $\sigma_C \propto Z$	Two-photon Compton scattering $\propto Z$
Interactions with nucleus or bound nucleons	Nuclear photoelectric effects: reactions ( $\gamma, n$ ), ( $\gamma, p$ ) photofission $\propto Z$ ( $E \geq 10 \text{ MeV}$ )	Nuclear coherent scattering ( $\gamma, \gamma$ ) $\propto Z^2$	Nuclear Compton scattering ( $\gamma, \gamma$ ) $\propto Z$	
Interactions with electrical field surrounding charged particles	(1) Electron–positron pair production in field of nucleus $K \propto Z^2$ ( $E \geq 1.02 \text{ MeV}$ ) (2) Electron–positron pair production in electron field $\propto Z$ ( $E \geq 2.04 \text{ MeV}$ ) (3) Nucleon–antinucleon pair production ( $E \geq 3 \text{ GeV}$ )	Delbrück scattering $\propto Z^4$		
Interactions with mesons	Photomeson production ( $E \geq 150 \text{ MeV}$ )	Coherent resonant scattering ( $\gamma, \gamma$ )

**Table 2** The relationship between the attenuation coefficients

Coefficient	Relationship	Units	Units in which thickness is measured
Linear ( $\mu^*$ )		$\text{m}^{-1}$	m
Mass ( $\mu$ )	$\mu^*/\rho$	$\text{m}^2 \text{kg}^{-1}$	$\text{kg m}^{-2}$
Atomic	$(\mu^*/\rho) Z/N_0$	$\text{m}^2 \text{atom}^{-1}$	$\text{atom m}^{-2}$
Electronic	$(\mu^*/\rho) 1/N_0$	$\text{m}^2 \text{electron}^{-1}$	$\text{electron m}^{-2}$

$N_0$  is the number of electrons per kilogram,  $Z$  is the atomic number, and  $\rho$  is the density of the absorber ( $\text{kg m}^{-3}$ ).

incident photon

$$\sigma_{\text{tot}} = \tau + \sigma_{\text{R}} + \sigma_{\text{C}} + K \quad [1]$$

Table 2 shows the relationship between various kinds of attenuation coefficients applied in practical calculations.

It should be emphasized that the absorption coefficient is a much more restricted concept than the attenuation coefficient. Attenuation also includes the purely elastic process in which the photon is merely deflected and does not give up any of its initial energy to the absorber. In a photoelectric interaction, the entire energy of the incident photon is absorbed by an atom of the medium, while in the Compton effect, some energy is absorbed and appears in the medium as the kinetic energy of a Compton recoil electron; the balance of the incident energy is not absorbed and is present as a Compton scattered photon.

The primary effect of the interaction of X-rays with matter includes the production of high-energy electrons, which are the main agents through which all the effects of X-rays arise.

For narrow, parallel, and monochromatic photon beams, the attenuation in homogeneous matter is given by the exponential law

$$I = I_0 e^{-\mu^* t} \quad [2]$$

where  $I$  is the transmitted intensity,  $I_0$  is the incident intensity, and  $t$  is the absorber thickness (in meters).

The linear attenuation coefficient  $\mu^*$  is closely related to the so-called half-value thickness  $D_{1/2}$ , which reduces the intensity of a narrow X-ray beam to one-half of its original value ( $\mu^* = 0.693/D_{1/2}$ ).

If the absorber is a mixture or a chemical compound, its mass attenuation coefficient  $\mu$  can be calculated from the 'mixture rule'

$$\mu = \sum_{i=1}^n W_i \mu_i \quad [3]$$

where  $W_i$  and  $\mu_i$  are the weight fraction and mass attenuation coefficient for the  $i$ th element, respectively, and  $n$  is the total number of the elements in the absorber.

For broad photon beams, the attenuation is no longer exponential and is given by

$$I = I_0 e^{-\mu^* t} B(t, h\nu, A, L) \quad [4]$$

where  $B(t, h\nu, A, L)$  is the so-called build-up factor, which depends on the thickness, photon energy, area of the absorber, and the absorber-detector distance. The factor takes into account scattered photons and is defined as the ratio of the observed effect to the effect produced by the primary radiation alone. It is usually obtained experimentally and its value can range from 1 to over 100.

### Photoelectric Absorption

This effect involves the disappearance of a radiation photon and the photoelectric ejection of one bound electron from the absorbing atom, leaving the atom in an excited state. The kinetic energy of the ejected photoelectron is given by the difference between the photon energy  $h\nu$  and the atomic binding energy of the electron  $E_c$  (called ionization energy). Figure 1 shows the mass attenuation coefficient for the photoelectric process as a function of photon energy for water (representing a low atomic number material) and for lead (representing a high- $Z$  material). The discontinuities appear at the energies corresponding to the energies of the absorption edges. The probability of ejection is a maximum if the photon has just enough energy to knock the electron from its shell. The photoelectric cross-section varies with photon energy approximately as  $(h\nu)^{-3}$ . In tissue, the average energy transferred per interaction  $\bar{E}_{\text{tr}}$  is equal to the average energy absorbed per interaction  $\bar{E}_{\text{ab}}$  and nearly equal to the energy of the incident photon  $h\nu$ . In consequence, the transfer ( $\mu_{\text{tr}}^* = \mu^* \bar{E}_{\text{tr}}/h\nu$ ), absorption ( $\mu_{\text{ab}}^* = \mu^* \bar{E}_{\text{ab}}/h\nu$ ), and the attenuation ( $\mu^*$ ) coefficients are nearly equal.

When the apparently sharp X-ray absorption discontinuities are examined at high resolution, they are found to contain a fine structure that extends, in some cases, to about a few hundred electron volts above the absorption edge. The fine structure very close to an absorption edge (less than  $\sim 30$  eV above the edge) is generally referred to as a Kossel structure, while the so-called extended fine structure (Kronig structure) extends to  $\sim 300$  eV above the absorption edge (occasionally to  $\sim 1$  keV above an edge). The modulations of the absorption coefficient in the energy range above an absorption edge can be described theoretically in terms of the electronic parameters and through a Fourier transform relationship are closely related to the radial distribution function around the nucleus of the element of interest.

**Figure 1** Relationship of the mass attenuation coefficient for the photoelectric process versus photon energy. The lower inset shows in greater detail the change in the attenuation coefficient at the K absorption edge for lead. ### Compton Scattering

Compton (incoherent) scattering is the interaction of a photon with a free electron that is considered to be at rest. The process is the most important interaction mechanism in tissue-like materials. From conservation of momentum and energy, the following equations are derived:

$$h\nu' = \frac{h\nu}{1 + \gamma(1 - \cos \theta)} \quad [5]$$

$$T = h\nu - h\nu' = h\nu \frac{\gamma(1 - \cos \theta)}{1 + \gamma(1 - \cos \theta)} \quad [6]$$

$$\tan \phi = \frac{1}{1 + \gamma} \cot(\theta/2) \quad [7]$$

with

$$\gamma = \frac{h\nu}{m_0 c^2} \quad [8]$$

where  $h\nu$  and  $h\nu'$  are the energies of the incident and scattered photon, respectively,  $\theta$  is the angle between the directions of travel of the photon before and following a scattering interaction,  $T$  and  $\phi$  are the kinetic energy and scattering angle of the Compton recoil electron, respectively, and  $m_0$  is the rest mass of the electron.

### Probability of Compton Collision

The differential Klein–Nishina collision cross-section  $d\sigma_{KN}/d\Omega$  is defined as the ratio of the number of photons scattered in a particular direction to the number of incident photons. For unpolarized photons

scattered on unbound, randomly oriented electrons,  $d\sigma_{KN}/d\Omega$  is given by

$$\frac{d\sigma_{KN}}{d\Omega} = \frac{r_0^2}{2}(1 + \cos^2 \theta) F_{KN} \left[ \frac{\text{cm}^2}{\text{electron sr}} \right] \quad [9a]$$

with

$$F_{KN} = \left( \frac{1}{1 + \gamma(1 - \cos \theta)} \right)^2 \times \left( 1 + \frac{\gamma^2(1 - \cos \theta)^2}{(1 + \cos^2 \theta)[1 + \gamma(1 - \cos \theta)]} \right) \quad [9b]$$

where  $r_0$  is the classical radius of the electron equal to  $2.818 \times 10^{-15}$  m. For low energies of incident photons (less than a few tens of kilo electron volts), the angular distribution of Compton-scattered photons is symmetrical  $\sim \theta = 90^\circ$ ; at higher energies, the Compton scattering becomes predominantly in the forward direction.

The fraction of energy transferred to the kinetic energy of a recoil electron in each Compton interaction can be calculated from

$$\frac{d\sigma_{tr}}{d\Omega} = \frac{r_0^2}{2}(1 + \cos^2 \theta) F_{KN} \frac{\gamma(1 - \cos \theta)}{1 + \gamma(1 - \cos \theta)} \quad [10]$$

The energy transfer coefficient  $\sigma_{tr}$  is obtained by integrating eqn [10] over all scattering angles.

The total incoherent (Compton) collision cross-section per atom  $\sigma_C$  involving the so-called electron binding corrections is given by

$$\sigma_C = \frac{r_0^2}{2} \int_0^\pi (1 + \cos^2 \theta) F_{KN} \times S(x, Z) 2\pi \sin \theta d\theta \quad [11]$$

where  $S(x, Z)$  is the incoherent scattering function, which depends upon  $x = \sin(\theta/2)/\lambda$  and atomic number  $Z$ ; the values of  $S(x, Z)$  and  $\sigma_C$  are available in the literature.

In summary, it should be emphasized that (a) the Compton process is almost independent of atomic number; (b) its probability decreases with increase of the photon energy; (c) the fraction of the energy transferred per collision to the kinetic energy of a recoil electron increases with increase in photon energy; and (d) in soft tissue, the Compton process is much more important than other interaction processes for photons in the range 100 keV to 10 MeV.

### Rayleigh Scattering

This is a process by which photons are scattered by bound atomic electrons and in which the atom is neither ionized nor excited. The incident photons are

scattered with unchanged frequency and the scattered waves from electrons within the atom combine with each other. The interference is always constructive, provided the phase change over the diameter of the atom is less than one-half a wavelength, i.e., whenever

$$(4\pi/\lambda)r_a \sin(\theta/2) < 1 \quad [12]$$

where  $r_a$  is the effective radius of the atom. Rayleigh scattering is thus a cooperative phenomenon and is hence called coherent scattering. The process mainly occurs in the forward direction, at low energies, for large  $Z$  values, and is described by the differential cross-section  $d\sigma_R/d\Omega$ , i.e.,

$$\frac{d\sigma_R}{d\Omega} = \frac{r_0^2}{2}(1 + \cos^2 \theta) [F(x, Z)]^2 \quad [13]$$

where  $F(x, Z)$  is the atomic form factor.

The total coherent (Rayleigh) scattering cross-section per atom  $\sigma_R$  can be calculated from

$$\sigma_R = \frac{r_0^2}{2} \int_{-1}^1 (1 + \cos^2 \theta) [F(x, Z)]^2 2\pi d(\cos \theta) \quad [14]$$

The values of  $F(x, Z)$  and  $\sigma_R$  are tabulated in the literature.

### Pair Production

When the energy of the incident photon is greater than 1.02 MeV, the photon may be absorbed through the mechanism of pair production. When the photon passes near the nucleus of the atom and is subjected to the strong field of the nucleus, it may suddenly disappear as a photon and be transformed into a positive and negative electron pair with kinetic energies equal to  $h\nu - 2m_0c^2$ . The positron excites and ionizes atoms as it travels through matter in the same way as an electron until it is finally brought to rest. Then the positron combines with one of the free electrons abundant in matter and is annihilated; two annihilation photons, each of 0.511 MeV, are finally produced. The pair production cross-section increases rapidly with increase in energy above the threshold of 1.022 MeV.

### Total Attenuation Coefficient

As already mentioned, the total attenuation coefficient is the sum of the attenuation coefficients for each interaction process (eqn [1]). The percentage contribution of each process to the total attenuation changes with photon energy and depends on the atomic number of a single element absorber or the so-called effective atomic number in case of complex materials.

## Diagnostic Use of X-Rays

### Attenuation of X-Rays in the Patient

The different tissues in the patient attenuate the X-rays in different ways and therefore the information carried by the transmitted X-rays can be used to visualize the internal structures. From the standpoint of opacity to X-rays, all anatomical structures encountered in clinical radiology can be classified according to their effective atomic numbers into three categories: adipose tissues (fat); soft tissues (with the exclusion of fat) and body fluids; and bone.

The effective atomic number is a convenient parameter for defining the X-rays attenuation properties of a complex medium as a biological tissue, and particularly for the calculation of dose in radiography. The concept of the effective atomic number is based on a proportional relation of the elemental cross-section per atom to  $Z^m$  where  $m$  depends on the process considered. For a specific interaction the atomic cross-section of an element is generally expressed as

$$\sigma = K(E)Z^m \quad [15]$$

The  $m$  values for a tissue vary in the range 4–5 for the photoelectric effect; 2–3 for the coherent (Rayleigh) scattering;  $\sim 1$  for the incoherent (Compton) scattering.  $K(E)$  is a function of photon energy for each partial process. For a specific interaction the mass attenuation coefficient for the individual element is given by

$$\begin{aligned} \frac{\mu^*}{\rho} &= \sigma \left( \frac{N_A}{A} \right) = K(E)Z^m \left( \frac{N_A}{A} \right) \\ &= K(E)N_0Z^{m-1} \end{aligned} \quad [16]$$

$$N_0 = Z \frac{N_A}{A} \quad [17]$$

where  $N_A$  and  $A$  are the Avogadro's constant ( $6.02214199 \times 10^{23} \text{ mol}^{-1}$ ) and the atomic weight, respectively;  $N_0$  is the number of electrons per unit mass of the element of atomic number  $Z$ . Thus for a mixture with an effective atomic number  $\bar{Z}$ , the following relation is fulfilled:

$$\left( \frac{\mu^*}{\rho} \right)_{\text{mix}} = K(E)N_{\text{mix}}\bar{Z}^{m-1} \quad [18]$$

where  $N_{\text{mix}}$  is the number of electrons per unit mass of the mixture. Considering the three main interaction processes which contribute to the total attenuation of X-rays, that is the photoelectric effect, coherent and incoherent scattering, the total mass

attenuation coefficient for a complex medium is given by

$$\begin{aligned} \left( \frac{\mu^*}{\rho} \right)_{\text{mix}} &= N_{\text{mix}} [K_a(E)\bar{Z}_a^{m_a-1} + K_R(E)\bar{Z}_R^{m_R-1} \\ &\quad + K_C(E)\bar{Z}_C^{m_C-1}] \end{aligned} \quad [19]$$

where  $K_a$ ,  $K_R$ , and  $K_C$  are energy-dependent functions for photoelectric effect, coherent, and incoherent scattering, respectively,  $m_a$ ,  $m_R$ , and  $m_C$  are the individual exponents for these processes, and  $Z_a$ ,  $Z_R$ , and  $Z_C$  are the effective partial atomic numbers for the corresponding processes given by

$$\bar{Z}_a = \left[ \sum_i \alpha_i Z_i^{m_a-1} \right]^{1/(m_a-1)} \quad [20a]$$

$$\bar{Z}_R = \left[ \sum_i \alpha_i Z_i^{m_R-1} \right]^{1/(m_R-1)} \quad [20b]$$

$$\bar{Z}_C = \left[ \sum_i \alpha_i Z_i^{m_C-1} \right]^{1/(m_C-1)} \quad [20c]$$

where  $\alpha_i$  is the fractional electron content of the  $i$ th element in the mixture. The total effective atomic number of the mixture  $\bar{Z}$  is obtained from the following relation:

$$\begin{aligned} K_a(E)\bar{Z}_a^{m_a-1} + K_R(E)\bar{Z}_R^{m_R-1} + K_C(E)\bar{Z}_C^{m_C-1} \\ = K_a(E)\bar{Z}_a^{m_a-1} + K_R(E)\bar{Z}_R^{m_R-1} + K_C(E)\bar{Z}_C^{m_C-1} \end{aligned} \quad [21]$$

The effective atomic numbers for bone, muscle, and water are shown in Table 3. In the soft X-ray energy region,  $E < 150 \text{ keV}$ , the total effective atomic number practically does not depend on the photon energy.

### Radiological Image

Figure 2 explains how the primary radiological image is produced. Since the eye is insensitive to X-rays, this image is converted to a visible image by a fluorescent screen, image intensifier, or film (see Figure 3). The conversion of X-ray energy to light is based on the fluorescence and phosphorescence of certain crystals, such as  $\text{CaWO}_4$ ,  $\text{CsI:Na}$ ,  $\text{BaSrSO}_4$ ,  $\text{GdO}_2\text{S:Tb}$ , etc. In computed radiography the image receptor is a storage screen, coated with europium-activated barium halide crystals. Radiation increases the energy of some of the electrons in the crystal lattice, which are held in 'traps'. This creates a latent image that can be read out later in a readout unit by scanning the storage screen line-by-line with a laser beam. The resulting luminescence is detected by

a photomultiplier, amplified electronically, and converted into digital value.

The new imaging systems use a direct digital radiography method based on flat panel detectors. The flat panel detector consists of a scintillation layer mounted on a pixel readout photodiode matrix made of amorphous silicon. Each pixel of the matrix is connected to a row line for driving voltages and to a column line for readout via an active switching element, which may be either a thin-film diode or a thin-film transistor. The electric charges are read out in parallel for one row. The signals are then multiplexed and converted to digital format inside the detector housing. The data are transmitted via a fiber optic link to the acquisition system, where digital processing is performed. A schematic view of the internal construction of the flat panel detector is shown in **Figure 4**. The flat-panel exposures are significantly better than those obtained by conventional screen–film combinations.

To visualize many organs in the body that are characterized by the same attenuation of X-rays, it is necessary to introduce into the patient a contrast medium that is deposited in the organ of interest and which absorbs X-rays either more or less than the surrounding tissues. The sensitivity to contrast agents such as iodine can be enhanced by two or more orders of magnitude by noting the difference between two exposures made with monochromatic X-ray beams, one beam with energy just above the absorption edge and the other with energy just below it. Such beams can be readily produced using synchrotron radiation. For example taking the difference between the two images enhances the contrast between the blood vessels carrying the iodine and the other tissues of the body. This dual-energy subtraction technique may make it possible to image the coronary arteries in less time and with a much smaller iodine concentration than is needed for conventional angiography. The dual-energy X-ray absorptiometry (DEXA) is widely used for measuring bone mineral density in osteoporosis diagnosis. DEXA uses two X-ray beams of different energy to estimate the bone density based on the differences in the absorption of X-rays in bone and soft tissue. This fast method uses very low doses of radiation and can measure as little as 2% of bone loss per year.

Certain radiographic examinations require the visualization of soft, sometimes calcified, tissue lesions that are surrounded by soft tissue. A typical example of such examination is mammography, where the breast is examined radiographically mainly to reveal neoplastic and benign lesions. Since the radiographic examinations require high soft-tissue contrast and high absorption of X-rays in calcium, low-energy X-ray beams are used, e.g., produced by synchrotron facilities (digital mammography).

## Tomography, Nondestructive Testing, and Detection of Illicit Materials

In conventional tomography (from the Greek *tomos* meaning section), the confusing shadows cast by the overlying and underlying structures are blurred out, whilst those of the structures of interest are left

sharply defined and therefore visible. To achieve this selective blurring it is necessary to have a controlled, accurate, relative movement of the X-ray tube, film, and patient during the exposure. The simplest tomographic movement is that due to Twyman and is what is known as a linear tomographic movement. The X-ray tube is moving along a line and the film in

**Figure 4** Construction of the flat-panel detector. The X-ray sensitive layer consists of cesium iodide (CsI). The amorphous silicon sensor array comprises  $3000 \times 3000$  pixels. (Reproduced with permission from Hamers S and Freyschmidt J (1998) Digital radiography with an electronic flat-panel detector: First clinical experience in skeletal diagnostics. *Medicamundi* 42: 2–6; © Medicamundi.)

the opposite direction along a parallel straight line. The tomographic apparatus is constructed so that this exact relative movement of film and X-ray tube occurs. The shadows of all objects in the plane of cut (also called the in-focus plane) parallel to the plane of movement of the film will be free from tomographic blurring, while objects outside the plane will have blurred shadows. The tomographic apparatus is designed in such a way that it is possible to place the plane of cut at any desired level in the patient.

More effective blurring out of the shadows of overlying and underlying objects and a possibility of obtaining thinner cuts than those provided by linear tomographic movement can be achieved by using more complex movements, such as circular, elliptical, or hypocycloidal.

In computed tomography (CT), the information contained in the absorption measurements is fully utilized and the sensitivity is improved as compared to the conventional tomography. In CT imaging, the cross-sectional distribution of the linear attenuation coefficient within investigated object is reconstructed mathematically from its projections obtained by X-ray attenuation measurements. This is illustrated in **Figure 5**. From a mathematical standpoint, the solution to the problem of how to reconstruct a function from its projections dates back to 1917; however, the first tomographic scanner was constructed by Hounsfield in 1971, acknowledged by a Nobel prize in 1979, together with Allan Cormack who independently discovered some algorithms used in CT image reconstruction.

There are several types or generations of X-ray tomographic scanners operating in different acquisition geometries:

1. First generation parallel-beam geometry scanners: the measurements of X-ray transmission are obtained using a single highly collimated pencil beam and detector. The beam is translated in a linear motion across the patient to obtain a projection profile. The

source and detector are then rotated around the patient by  $\sim 1^\circ$ , and another projection profile is obtained. This translate–rotate scanning motion is repeated until the source and detector have been rotated by  $180^\circ$ . The highly collimated beam provides excellent rejection of radiation scattered in the patient; however, the complex scanning motion results in long ( $\sim 5$  min) scan time. This geometry was used by Hounsfield in his original experiments, but is not used in modern scanners.

2. The second generation scanners: a narrow fan beam of X-rays and linear array of detectors are used. A translate–rotate scanning motion is still employed; however, a large rotation increment is used, which results in shorter scan times.

3. The third generation scanners: a fan beam of X-rays is rotated  $360^\circ$  around the patient. A curved detector array consisting of several hundred of independent detectors is mechanically coupled opposite to the X-ray source, and both rotate together. No translation motion is used. The fan beam must be wide enough to completely contain the patient. The projection data for a single image are acquired in as little as 1 s.

4. The fourth generation scanner: the fan beam X-ray source rotates around the patient, while the detector array remains stationary. The detector array consists of several hundred up to several thousand independent detectors mounted on a circle that completely surrounds the patient. Scan times are similar to those of third generation scanners. The detectors are no longer coupled to the X-ray source and hence cannot make use of focusing to reject scattered radiation. However, detectors are calibrated twice during each rotation of X-ray source, providing a self-calibrating system.

5. Cine CT scanners: the X-ray source is an integral part of the system design. The detector array remains stationary, while a high-energy electron beam is electronically swept along a semicircular tungsten strip anode. X-rays are produced at the point where the electron beam hits the anode, resulting in a source of X-rays that rotates about the patient with no moving parts. Projection data can be acquired in  $\sim 50$  ms, which is fast enough to image the beating heart without significant motion artifact.

6. Helical (spiral) CT scanners: they allow for fast multiple scans for obtaining three-dimensional images. This is achieved by acquiring projections while the patient is translated through the geometry in a smooth continuous motion rather than stopping for each image. Projection data for multiple images covering a volume of the patient can be acquired in a single breath hold at rates of approximately one slice per second.

**Figure 5** Projections,  $P(t, \theta)$ , obtained from X-ray attenuation measurements are used in computed tomography to reconstruct the cross-sectional distribution of the linear attenuation coefficient within investigated object.

The thickness of the selected section of a tissue examined by a CT device is usually between 2 mm and 1 cm and varies depending on the requirements of each clinical study. To enhance the contrast of CT various commercially available oral or intravenous contrast media can also be applied.

Recently, computed microtomography has been developed using either conventional X-ray tubes or a synchrotron source. The latter gives superior spatial resolution and shorter data acquisition times because of its high brilliance and continuous X-ray spectrum. The micro tomographic imaging at synchrotron sources can be combined with other techniques such as X-ray absorption near-edge spectrometry, X-ray fluorescence, X-ray diffraction to obtain high resolution three-dimensional images of the object. A typical synchrotron based micro tomographic imaging setup is shown in **Figure 6**.

Industrial radiography (or microradiography) is one of the best known and most common practical

applications of X-rays. The principles of the technique are the same as for medical diagnostic radiography and are based on the direct consequences of differential absorption of X-rays by matter of varying homogeneity, thickness, and density. Photographic film or digital flat-panel detector applied for the detection translates the amount of radiation that penetrates a sample into a two-dimensional picture of the interior of the opaque material. It is worth mentioning that in radiography other kinds of radiation can also be used, such as  $\gamma$ -rays,  $\beta$ -particles,  $\alpha$ -particles, and neutrons. Radiography gives information about the entire sample body, showing diverse phases, segregations, inclusions, and internal voids. It can be used in the inspection of process equipment for gross conditions, such as the position of a frozen valve, for determining the extent of corrosion or scale build-up inside piping or metal containers, and for detection and location of flaws in metal welding and the casting of metal parts. In the last application radiography can

**Figure 6** Schematic view of a typical synchrotron-based computed microtomography setup.

be used as a tool for the development of proper welding or casting techniques or in the control of weld or casting quality. Radiography can also be performed for dynamically changing systems. This is achieved by high-speed digital X-ray radiography systems based on a microcolumnar CsI(Tl) scintillator optically coupled to a charge coupled device. Such systems can take radiographic images with a resolution of  $\sim 250 \times 250$  and a speed up to  $10^5$  frames per second.

Recently, the X-rays have widely been used for detecting explosives and illicit materials to prevent terrorism and smuggling. The scanners based on X-ray attenuation are the most commonly used means to inspect luggage at the airports. They provide information on the object density and effective atomic number. Several types of scanners are in use. Among them the most common are the conventional transmission X-ray scanners. The scanner generates a fan-shaped X-ray beam whose attenuation in the object is measured by line array of detectors. From the absorption data a high quality image is produced. However, such scanners cannot distinguish between thin sheet of a strong absorber and thick slab of a weak absorber. In **Figure 7** some example images obtained with a conventional X-ray scanner are shown. Another type is a dual-energy X-ray scanner in which the X-rays of energy above 100 keV and  $\sim 80$  keV are used. The absorption of the lower energy X-rays depends mainly on the effective atomic number as well as on the thickness of the material. The absorption of the higher energy beam depends mainly on the density of the material. By combining both images a distinction between organic (low  $Z$ ) and inorganic/metal (high  $Z$ ) objects can be made. For detecting explosives scatter imaging scanners are employed. Image data are collected from backscattered X-rays. The backscattered image is sensitive for low- $Z$  high-density materials such as plastic explosives. **Figure 8** shows a relation between the effective atomic number and the

**Figure 7** Some example images of the conventional X-ray scans of luggage at airports. (Reprinted with permission from Singh S and Singh M (2003) Review. Explosives detection systems (EDS) for aviation security. *Signal Processing* 83: 31–55; © Elsevier.)

density for explosives and several other materials. The most advanced systems are the three-dimensional imaging scanners based on CT principle.

Another example of the practical application of X-ray absorption is the determination of porosity, density, and thickness, including also the control of thin coatings. **Figure 9** shows the principle of a coating thickness measurement. In this case the thickness of tin plate upon steel is not measured by the attenuation of the incident polychromatic beam, but this beam excites the characteristic X-ray lines of the substrate after the beam has gone through film, and finally the attenuation of the iron characteristic X-rays leaving the substrate is used to determine the thickness of the tin film.

The absorption of X-rays is also used in food industry to decrease the population of or prevent the

**Figure 8** Relationship between the effective atomic number and density for different materials. (Reprinted with permission from Singh S and Singh M (2003) Review. Explosives detection systems (EDS) for aviation security. *Signal Processing* 83: 31–55; © Elsevier.)

**Figure 9** Determination of the thickness of tin plate on steel substrate.

growth of undesirable biological organisms in food. This is achieved by depositing the X-ray energy in the irradiated product. The X-rays are generated by using accelerators in which kinetic energy of electrons is converted into well penetrating X-rays (bremsstrahlung). X-rays provide a better dose deposition uniformity in the products with larger areal densities as compared to a direct electron beam.

## Qualitative and Quantitative Measurements

Immediately after discovering X-rays, Röntgen laid the foundation for X-ray absorptiometry with polychromatic beams; this can be compared to colorimetry or photometry with white light. As all atoms absorb X-rays, the method is not specific for any element or group of elements. Polychromatic X-ray beams are

strong and complex and can be used with relatively simple equipment for instantaneous intensity measurements. Through the determination of the energies for which the minimum intensities of transmitted X-rays are observed, it is possible to identify the absorption edges of the elements present. To use absorptiometry with polychromatic beams for the quantitative characterization of materials it is necessary to recourse to the so-called effective wavelength of a polychromatic beam, a concept involving some difficulties.

In X-ray absorptiometry with monochromatic beams, the attenuation at various wavelengths can be measured on both sides of an absorption edge. The results obtained enable (1) the location of the absorption edge and thus the identification of the element, and (2) the calculation of the height of the 'jump' and thus the determination of the concentration of the element of interest. The absorption edge method has been used, for example, for the determination of bromine in liquid samples.

## X-Ray Preferential Absorption Analysis

The method is based on the measurement of the transmitted X-ray intensities at one or more energies. The sensitivity of the analysis depends on the selective absorption of X-rays by the element of interest compared with the absorption by the sample matrix. Assuming that the sample consists of a matrix and an analyte, the concentration of the wanted element  $W_i$  is given by

$$W_i = \frac{[\ln(I_0/I)/\rho t] - \mu_M}{\mu_i - \mu_M} \quad [22]$$

where  $\mu_i$  and  $\mu_M$  are mass attenuation coefficients for the wanted element and the matrix, respectively. The concentration of the analyte can thus be determined if the mass per unit area ( $\rho t$ ) of the sample is known, and  $\mu_M$  is approximately known or the composition of the matrix is constant. To eliminate  $\rho t$  from eqn [22], it is necessary to measure the transmission of narrow X-ray beams at two different energies. In the dual-energy X-ray (or  $\gamma$ -ray) transmission method, the concentration of the analyte is given by

$$W_i = \frac{-(\mu'_M - R\mu''_M)}{[(\mu'_i - \mu'_M) - R(\mu''_i - \mu''_M)]} \quad [23a]$$

where

$$R = \frac{\ln(I_0/I)'}{\ln(I_0/I)''} = \frac{(\mu'_i - \mu'_M)W_i + \mu'_M}{(\mu''_i - \mu''_M)W_i + \mu''_M} \quad [23b]$$

and prime and double prime refer to the first and second energies, respectively. The analysis is accurate when the ratio  $\mu'_M/\mu''_M$  is constant for all possible compositions of sample matrix, which occurs when the X-ray energies are just above and

below the K shell absorption edge of the element of interest. In general, to perform quantitative analysis of a multielement sample by using the X-ray preferential absorption technique it is necessary to use either the same number of sources as unknowns or one less source than unknowns plus a measurement of the sample density thickness.

A similar dual-measurement approach is used in tomography, where by subtraction of two tomograms obtained for X-rays of energy above and below an elemental absorption edge, a map of concentration of that element is produced. The differential tomography technique is valuable for study of major and minor elements to the 0.1% level.

## Other Applications

Although it is impossible to be fully comprehensive and moreover, some examples of applications of X-ray absorption techniques have already been mentioned to illustrate a specific method described, a few additional examples merit mention. In the field of thickness determination, X-ray absorption techniques are used in a variety of applications: such as study of zinc coating on steel, cladding thickness of nuclear fuel elements, plate metals on plated wires, electrolytic silver, iron–nickel films, chromium plating on molybdenum, titanium on Kovar, wall thickness of aircraft propellers, control of thickness and weight of inorganic coatings on paper. Other examples of application of X-ray absorptiometry include: sulfur content of crude and refined oil, tetraethyl lead content of gasoline, additives in heavy-duty lubricating oils, ash content and quality of coal, heavy-metal content of glass, chlorine and fluorine content of polymers and plastics, bromine content in gaseous brominated derivatives, determination of formula of organic compounds (C, H, O), concentration of fillers and impregnants in wood, paper, cloth, rubber, carbon, etc., mineral content and efficiency of softening of water, soil

composition, absorbed contents of charcoals and silica gels, concentration of reagent solutions containing metallic ions, alloy analysis, and histochemical analysis.

Medical diagnostic X-ray radiography and tomography are extensively used in many areas of medicine as excellent diagnostic tools, while industrial radiography has contributed tremendously to our knowledge of metallurgy, metal fabrication, and the internal structure of various materials.

## X-Ray Diffraction – Powder

**S Garcia-Granda and J M Montejo-Bernardo,**  
Universidad de Oviedo, Oviedo, Spain

© 2005, Elsevier Ltd. All Rights Reserved.

## Introduction

The diffraction of X-rays by crystalline materials provides a wide spectrum of tools for the study of solids, ranging from qualitative analysis to the study

of internal defects in the atomic arrangement. The techniques addressed in this article may be described collectively as ‘powder’ methods. These techniques apply to the study of polycrystalline materials whether they are in powder form, as supplied by nature or process, or in compacted form, as pellets or metallic mass.

X-ray powder-diffraction experiments involve the interpretation of the powder pattern considering the position (Bragg angle  $\theta$  or interplanar spacing  $d_{hkl}$ )

and the intensities of the diffraction maxima, the so-called lines or peaks.

## Basic Theory and Instrumental Design

### Angle-Dispersive Technique

A single crystal, when exposed to monochromatic X-rays, produces diffraction maxima according to the Bragg relationship  $n\lambda = 2d \sin \theta$ . The Bragg angle,  $\theta$ , is the angle between the primary X-ray beam (with  $\lambda$  wavelength) and the family of lattice planes, with interplanar spacing  $d$ ;  $n$  is an integer. In this process, the incident beam, normal to the diffracting plane, and the diffracted beam lie in a plane. If the crystal is rotated about the axis of the X-ray beam, a cone of diffracted rays is generated, the apex of the cone being at the crystal and its solid angle being equal to  $4\theta$ . The same cone of diffracted beams might be achieved by dividing the crystal into small segments and arranging them so that various increments of rotation about the X-ray beam axis are represented. By continuous subdivision of the crystal (within limits) one may arrive at a ‘powdered’ state that statistically furnishes all increments of rotation. Furthermore, the random positioning may be augmented by a rotation of the powdered specimen, usually about an axis normal to the beam. The cones of diffracted X-rays may be recorded by camera techniques using X-ray sensitive films or by diffractometer techniques using a suitable detector and its associated electronic equipment.

A flat photographic film placed perpendicular to the X-ray beam will record intersections of the diffraction cones, producing a pattern of concentric rings, i.e., a powder photograph. A strip of film placed about the sample will record arcs of these concentric rings, i.e., a Debye–Scherrer diagram. The powder diffractometer essentially adds an electronic device for counting the intensity on the arcs of the diffraction rings.

Figure 1 shows, in a simplified scheme, the geometry of a conventional diffractometer while Figure 2 shows a photograph of one of the many commercial diffractometers.

### Energy-Dispersive Technique

X-ray energy-dispersive diffraction (XED), introduced in the late 1960s, uses a primary X-ray beam of polychromatic (‘white’) radiation. In the case of powdered samples the photon energy (or wavelength) spectrum of the X-rays scattered through a fixed optimized angle is recorded using a semiconductor detector connected to a multichannel pulse-height analyzer. In XED powder work the incident- and

**Figure 1** Schematic representation of the geometry of a conventional powder diffractometer.

**Figure 2** Overall view and goniometer detail of a commercial powder diffractometer. (Courtesy of PANalytical.)

scattered-beam directions are determined by slits. The Bragg equation may be written in this case as  $2d \sin \theta_0 = \lambda = hc/E$  where  $E$  is the photon energy

associated with the Bragg reflection,  $h$  is Planck's constant, and  $c$  the speed of light.

## Sample Introduction Techniques

The shape of the average specimen is such that only rarely can it be directly placed into the diffractometer for analysis, so that special care has to be taken to achieve the random distribution of the crystallites to have meaningful peak intensities. The problems arising in sample preparation are: (1) Particle size. The powdered sample must consist of particles smaller than 5  $\mu\text{m}$ . Collection and separation of particles of these dimensions can be effected by sieving, sedimentation, or elutriation. (2) Surface flatness. Special precautions are needed to make the surface smooth and flat, with its plane including the diffractometer axis. If required, common binders, for instance, collodion, paraffin wax, or silicone grease, are applicable. (3) Preferred orientation. When it is necessary to ensure that the particles do not show preferred orientation, mix crushed glass or other amorphous medium with the powder or coat the plane surface of the sample carrier with a film of adhesive that dries at a moderate rate and then dust a layer of powder on the adhesive, poly(vinyl chloride), after it has become tacky.

The method of mounting the sample is of major importance. The 'standard' specimen holders furnished by the manufacturers are rectangular metal or plastic plates of about  $\sim 2$  mm thickness containing a rectangular window to hold the powdered sample. Specimen holders of this kind can be designed for loading samples from the front, edge, or back. Much accumulated experience tends to favor edge or back loading when preferred orientation needs to be minimized.

## Analytical Methodology

### Qualitative Analysis

Every crystalline powder produces a characteristic diffraction pattern. This is the basis of qualitative analysis by powder diffraction. Identification is usually accomplished by systematic comparison of an unknown pattern with a catalog of standard data such as the *Powder Diffraction File* published by the International Centre for Diffraction Data (ICDD). Specialized techniques have been designed for certain situations.

Diffraction patterns of mixtures consist of the superimposed patterns of the individual components. Therefore, powder diffraction is useful in analyzing mixtures as well as pure materials. As the number of

components increases, interpretation becomes more complicated because of the occurrence of peak superposition and success in interpretation depends on the amount of prior information available about the mixture.

As is true with all analytical procedures, X-ray powder diffraction is most powerful when used in conjunction with other techniques, such as emission spectroscopy, X-ray fluorescence spectroscopy, and chemical analysis. An important advantage of X-ray diffraction over these and other techniques is that the results obtained are in terms of the materials as they occur in the sample, not in terms of the elements or ions present. It is often the only satisfactory method of distinguishing among polymorphs or detecting a compound in the presence of others containing the same elements.

Furthermore, the sample is not consumed in X-ray diffraction analysis, so that it may be saved or subsequently analyzed by other techniques. The term 'nondestructive', frequently applied to X-ray analysis, is not always appropriate here because crushing, grinding, or other manipulations are frequently required to prepare the sample for powder diffraction.

### The X-Ray Powder Data File

The powder diffraction file (PDF) is a collection of single-phase X-ray powder diffraction patterns in the form of tables of the interplanar spacings ( $d$ ) and relative intensities ( $I/I'$ ) characteristic of each compound. Other information such as Miller indices, cell constants, and physical properties are included, when available, along with the references of the information source. The PDF has been used for more than six decades and the PDF-4 2003 release contains  $\sim 300\,000$  experimental and calculated patterns. The distribution and maintenance of the PDF are carried out by the ICDD, at Swarthmore, Pennsylvania, USA.

Each pattern is uniquely identified with a PDF number located on the upper left hand portion of the card. The set number is indicated by a two-digit field located to the left of the hyphen, and the digits located at the right identify the particular pattern. For instance, the pattern number 4-587 is the 587th pattern in set 4. The set number can also be used as an indication of the age of the set by adding 1950 to the set number. For the example given, the year of publication is  $(1950 + 4) = 1954$ .

Data on the card image contain the actual  $d$  (interplanar spacing)/ $I$  (relative intensity expressed as percentage of the strongest line) values and, where indexation has been done, the appropriate Miller indices. Additional data such as the formula and name

and mineral name of the compound, along with the experimental procedure and crystallographic and physical information, is also present.

### Search Procedures

Identification of samples can be made using the PDF or similar compilations. A search procedure commonly utilized is the Hanawalt method. The search manual is organized into 'groups' and 'subgroups'. Two lines from the table of '*d*' values and intensities serve to locate the 'entry' of the pattern in the manual. The *d* value of the strongest line of the pattern determines the group into which the entry falls, while the *d* value of the second strongest line determines the subgroup, that is, the location within the group. The entry also includes the next six strongest lines of the pattern in order of decreasing intensities.

Thus, to identify an unknown, we choose the first and second strongest lines of its diffraction pattern as the line-pair with which to look for a matching entry in the search manual. If the other six lines of such a qualifying entry also match lines in the unknown pattern, the identification is probably correct. The final step in the procedure is to confirm the identification by going to the PDF to check the complete pattern. In the more general case in which the pattern is that of a mixture of two or more phases, the manual solution can be tedious and unless carried out systematically, individual mistakes are likely. In the 'Hanawalt Work form' we choose from the table of diffraction pairs of lines to enter on the search manual. We then examine the remainder of the eight lines of any qualifying entry to check whether these lines also match lines of the unknown. We begin with the strongest line available and enter the search manual with line-pairs chosen in order of decreasing intensity until a qualifying entry is found. Once a phase is detected all its lines are 'deleted' and we continue the solution of the problem beginning with the strongest of the unaccounted lines. This work progresses until all lines of an unknown sample are satisfactorily matched.

Although the basic procedures for identifying phases by hand are reasonably well established, the inaccuracies in both the measured pattern and reference database generally make human judgment a necessary ingredient and this has prevented computerized algorithms from successfully automating the identification process. Most algorithms provide a restricted ordered list of candidate matches, but the experimenter must make the final selections and do the identification by hand. Recently, algorithms have been developed in an attempt to translate some of the pattern recognition capabilities commonly found in

human beings into a form convenient for automation. Much of the laborious work of manual searching, matching, and phase identification can now be performed routinely by computer.

### Quantitative Analysis

Powder X-ray diffraction has been applied to quantitative phase analysis (hereafter called QPA) for over 80 years. It seems that the first mention of QPA was made by Hull in the paper 'A new method of chemical analysis', published in 1919 in the *Journal of the American Chemical Society*. At this early stage, quantitative X-ray diffraction (QXRD) was based on a comparison of diffraction line intensities for the analyzed sample with a series of mixtures containing known amounts of the analyte.

The first use of an internal standard technique was reported in 1936 by Clark and Reynolds. Studies in the 1930s and the 1940s by Brentano, Shäffer, Taylor, and Brindley provided the basis for the appropriate corrections in the experimental intensities, particularly for absorption, and the microabsorption phenomena. (Grain-related effect occurs in polyphase samples. It occurs when large crystals preferentially interact with the beam, causing an appreciable reduction in the ratio of the diffracted intensities.)

The development and extension of QPA were facilitated by obtaining a large number of standard diffraction patterns of minerals and chemical compounds, thanks to the development of the powder camera by Debye and Scherrer (1916, 1917). Nevertheless, the take-off of phase quantification started in the late 1940s with the design and industrial manufacture of powder diffractometers and the formulation of a theoretical basis for quantitative analysis by Klug and Alexander in 1948.

In the 1980s, powder diffraction methods experienced a 'new age', due to the development of high intensity sources, better optics, and computerized diffractometers. This 'revolution' was also caused by the application of the Rietveld method to X-ray diffraction data.

QXRD analysis consists of determining the amount of a compound from measurements of intensity as the X-ray diffraction pattern of a mixture consists of the superposition of the diffraction patterns of its constituent compounds. As an example, the X-ray powder pattern of a binary mixture of crystalline antibiotics, along with the independent patterns of the two components, is shown in **Figure 3**.

### Basic Principles

In QPA, the basic equation that relates the X-ray intensity (of a diffraction peak *i*) of a phase *j* in a

**Figure 3** Powder pattern for a 1:1 binary mixture of two organic pharmaceutical samples showing the contribution of each individual pattern.

sample is

$$I_{ij} = \frac{K'_{ij}x_j}{\rho_j\mu^*} = \frac{K'_{ij}x_j}{\rho_j \sum_{k=1}^n \mu_k^* x_k} \quad [1]$$

where  $K'_{ij}$  is known as the calibration coefficient or calibration constant (and includes composition-independent terms). If the density of phase  $j$  is included in the calibration constant,  $K'_{ij}$ ,

$$I_{ij} = \frac{K_{ij}x_j}{\mu^*} = \frac{K_{ij}x_j}{\sum_{k=1}^n \mu_k^* x_k} \quad [2]$$

where  $x_j$  and  $\rho_j$  are the weight fraction and density of phase  $j$ ,  $\mu^*$  is the mass absorption coefficient of the sample, and  $x_k$  and  $\mu_k^*$  are, respectively, the weight fractions and absorption coefficients of the phases present in the sample.  $K'_{ij}$  is a product of several phase-related, instrument-related, and scattering-angle-related terms.

From determination of the  $x_j$ , the main objective of QPA, it is therefore necessary to:

1. measure the intensity  $I_{ij}$  (calculate the integrated intensity);
2. determine the absorption coefficient  $\mu^*$ ; and
3. determine the calibration constant  $K_{ij}$ .

Calibration is usually performed by preparation and measurement of analytical standards. There are several techniques to treat the dependence of the intensity on the absorption characteristics of the

sample. Absorption correction and calibration are often closely connected, and should be treated together.

### Diffraction–Absorption Technique

In this technique, it is assumed that the mass absorption coefficient  $\mu^*$  has been obtained (is known) by some other technique. Doing measurements on the pure phase  $j$  ( $x_j = 1$  and  $\mu_j^* = \mu^*$ ), we may obtain the calibration constant  $K_{ij}$ , and also  $x_j$ , by eqn [2]:

$$(I_{ij})_0 = K_{ij}/\mu_j^* \rightarrow K_{ij} = (I_{ij})_0\mu_j^* \rightarrow x_j = I_{ij}/(I_{ij})_0 \quad [3]$$

where  $(I_{ij})_0$  is the intensity of peak  $i$  of the pure phase  $j$ . In a multiphase sample, the weight fraction of a determined phase  $j$  is obtained combining eqns [2] and [3]:

$$x_j = \frac{I_{ij}\mu^*}{(I_{ij})_0\mu_j^*} \quad [4]$$

The pure phases must be available for the measurement of their  $(I_{ij})_0$  values.

### Internal-Standard Method

In this method, the sample analyzed is doped with a known amount of reference material, called the internal standard. The ratio of the intensities for the peak  $i$  of phase  $j$  and the peak  $h$  of the standard phase based on eqn [2] is

$$\frac{I_{ij}}{I_{hs}} = \frac{K_{ij}x_j}{K_{hs}x_s} \quad [5]$$

where  $x_j$  and  $x_s$  are the weight fractions in the doped sample. The weight fraction in the original sample ( $x_{j,0}$ ) is given by

$$x_{j,0} = x_j / (1 - x_s) \quad [6]$$

Equation [5] is the basic equation to all internal standard methods of X-ray quantitative analyses. It shows that the curve of the intensity ratio  $I_{ij}/I_{hs}$  obtained from mixtures of components  $j$  and  $s$  plotted against the weight ratio  $x_j/x_s$  is a straight line passing through the origin. The slope of this plot is a unique constant characteristic of components  $j$  and  $s$ , which is independent of the absorption characteristics of the specimen, or even the other components that may be present. An example of linear calibration can be seen in Figure 4.

### Reference Intensity Ratio (RIR)

In general, the RIR ( $I/I_c$ ) is defined as the ratio of the strongest peak of any phase  $j$  to the strongest corundum ( $\alpha$ -Al<sub>2</sub>O<sub>3</sub>) peak (113) in a mixture 1:1 by weight. RIR values are defined for Cu K $\alpha$  radiation and for Bragg–Brentano geometry, with a constant divergence slit. This ratio is ( $x_j = x_s = 0.5$  in eqn [5]):

$$(RIR)_j = I_{ij}/I_{hs} = K_{ij}/K_{hs} \quad [7]$$

Here, the subscript  $s$  refers to corundum, and the subscripts  $i$  and  $h$  refer to strongest peak of the phase  $j$  and corundum (the standard), respectively.

The most usual application of the RIR method is in the internal standard technique. Considering eqns [5]–[7]:

$$x_{j,0} = \frac{x_s}{1 - x_s} (RIR)_j \frac{I_{ij}}{I_{hs}} \quad [8]$$

If the internal standard is not corundum, but any other phase  $t$  (not present originally in the sample),

the relationship becomes

$$x_{j,0} = \frac{x_t}{1 - x_t} \frac{(RIR)_j}{(RIR)_t} \frac{I_{ij}}{I_{ht}} \quad [9]$$

which is the basis of the so-called matrix flushing method (the  $t$  phase is called the flushing agent, and in this context it works as an internal standard) and illustrates the application of the internal standard technique when information on matrix absorption is not available.

The application of this method to three-component samples is shown in Table 1.

### Other Complementary Methods

There are at least two other methods for quantitation of samples that are complementary: the dilution method and the addition method (also called the doping method). In the first, the sample is diluted with any inert material, preferably one with a known mass absorption coefficient. We can know the weight fraction of a phase  $j$  ( $x_j$ ) by measuring the intensity on the peak  $i$  in three samples: the original, the diluted, and the pure phase  $j$ . In this method, the pure phase is used also to obtain the calibration constant  $K_{ij}$ . This technique should be used for analysis of phases with medium or high abundance.

The addition method, however, is more adequate for the analysis of minor phases. This method is similar to the internal standard method but the sample to be analyzed is doped with a known amount of the same phase that is to be determined.

**Figure 4** Calibration line for determination of SiO<sub>2</sub> using KCl as internal standard.  $X_{SiO_2}$  represent the weight fraction of quartz in the sample.

### Full Patterns Methods

All the methods previously cited (and others like the external standard or standardless methods), based on intensity-concentration for single lines, are the traditional techniques used for QPA in the recent past; i.e., the RIR method (using either internal or external standards) is the most widely used. But today, with the availability of digitized diffraction information, full pattern fitting techniques have become more popular. The use of all reflections in a pattern minimizes the effects of preferred orientation, primary extinction, peak overlap, and nonlinear detection systems. The so-called whole-powder-pattern-fitting techniques have been the subject of great development in the last few years, and several procedures using whole-powder-pattern-fitting have been proposed for QPA:

1. using observed digitized whole-pattern traces (information preserved in the PDF database);
2. using whole-powder-pattern decomposition (WPPD); and
3. the Rietveld method.

The WPPD uses observed integrated intensities of standard reference patterns (these patterns have been previously decomposed into individual integrated intensities of Bragg reflections) to fit a determined sample or mixture of phases, refining the integrated intensity parameters, together with unit-cell and profile parameters, by least-squares or iteration, and also adjusting individual scale factors to obtain an overall fit. This procedure does not require knowledge of crystal structure parameters (site occupancy, positional, and thermal parameters) of phases in the mixture, and the weight fractions are obtained as a function of their scale factors and the mass-absorption coefficients of the respective phases (calculated from the chemical formula).

The Rietveld refinement was originally conceived as a method of refining crystal structures using powder neutron diffraction data. Later, it was extended to XRD patterns and phase abundance analysis in the 1980s and the 1990s. The method is based on the assumption that the measured diffraction pattern can be approximated by an analytical expression that contains instrumental and structural parameters (requires knowledge of site occupancy, positional, and thermal parameters), and on the idea that the XRD patterns should be analyzed using each point of the profile as a data point, rather than the integrated intensities of the individual peaks. This application has produced great advances in QPA, especially in accuracy and detection limits of weight fraction of phases (in fact, the detection of an analyte is possible

when its concentration is  $>0.5\%$  w/w, for minor concentrations, and a set of guidelines for the use of Rietveld refinement has been presented by the international Union of Crystallography Commission on Powder Diffraction.

In a sample with  $n$  phases, the weight fraction of phase  $k$  ( $w_k$ ), with a molecular weight  $M_k$  and with  $Z_k$  molecules in a cell of unit volume  $V_k$  is given by

$$W_k = \frac{S_k(ZMV)_k}{\sum_{i=1}^n S_i(ZMV)_i} \quad [10]$$

When an amorphous component is present in the sample, the values of the weight fractions (of crystalline phases) are overestimated to satisfy the normalization condition ( $x_i = 1$ ). So, an internal standard must be added ( $\leq 10\%$  in weight) to determine the absolute weight percentages of amorphous and crystalline phases. The amorphous content  $A(\%)$  is obtained by the small overestimation of the internal standard:

$$A(\%) = \frac{1 - (\omega_s/\varphi_s)}{100 - \omega_s} \times 10^4 \quad [11]$$

where  $\omega_s$  and  $\varphi_s$  are the real and the Rietveld analyzed weight fractions of the internal standard, respectively.

To analyze mixtures either with an amorphous phase or with phases for which structural parameters are unknown, in the last decade, several new techniques have been developed based on known methods.

In the combined Rietveld–RIR method, a known amount of corundum is added to the mixture, and the refined values of the Rietveld phase fractions are converted into weight fractions and rescaled to absolute values with respect to the amount of standard added. Another technique, combining the Rietveld and addition methods, can determine the absolute quantities of the phases, crystalline and amorphous. Here, the added standard is part of the original mixture.

For quantitative analysis of largely amorphous composites, an analysis based on the diffraction–absorption method was also developed. In this approach, the intensity scale factor and the microabsorption parameter are obtained by a calibration procedure based on the diffraction data of different samples of pure crystalline and mixtures. This information is used to calculate the crystalline weight fraction.

For quantifying individual phases in a mixture, a whole-pattern-profile-stripping method, based on the scale of standard profiles to strip them of the experimental pattern, may be used. The method produces a correct quantification for mixtures of components with similar linear absorption coefficients, and the

scale parameter of every phase is taken to represent its volume proportion in the mixture.

An alternative approach to mixtures that contain phases with unknown or imperfectly known crystal structures combines the whole-powder-pattern-decomposition method with the Rietveld analysis. The method includes a modification of the standard Rietveld approach.

Finally, a new method to determining the polymorphic composition in intact compacts, using parallel-beam X-ray powder diffractometry, has also been developed.

Today, QXRD methods are used for organic and inorganic compounds, macromolecules, polymers, drugs, zeolites, cements, catalysts, metals, ceramics, atmospheric aerosols (airborne particulates), fly ash, and minerals. The physical states of the materials can be powders, thin films, polycrystalline, and bulk materials.

### Sources of Error

A preferred orientation that favors the intensity of some line or lines of the diffraction spectrum due to deviations of the ideal random orientation of crystallites is perhaps the most serious problem limiting the quantitative analysis of complex mixtures. Although it is possible to accommodate preferred orientation during data analysis, it is preferable to utilize a procedure that minimizes or eliminates preferred orientation during sample preparation.

Choosing a representative standard is an important part of quantitative analysis. Although there are numerous factors that induce variability in standard data, the most important are composition and order/disorder variations. It is obviously very important to be certain that standards contain 100% crystalline material and no amorphous material.

Numerous authors have emphasized the effects of crystallite size on diffraction data and these effects include primary extinction for well-crystallized phases such as quartz and calcite, particle statistics, microabsorption, and preferred orientation.

The presence of broad, overlapping reflections represents a problem in most quantitative analyses of complex mixtures. The overlap may be of multiple reflections from one phase, making the use of a single reflection difficult, or it may more commonly be the overlap of two important reflections of different phases.

Amorphous materials yield broad, asymmetric peaks. Furthermore, different amorphous materials yield different broad diffraction bands. The difficulty of detecting even significant amounts of amorphous material by the presence of this broad peak and the large errors associated with measuring the integrated

intensity of these broad, asymmetric peaks influence the methods used to quantify amorphous materials.

Reasonable count times can yield detection limits of 0.05 wt% (500  $\mu\text{g}$  per g) for ZnO with an RIR of 4.35. Detection limits <500  $\mu\text{g}$  per g can easily be achieved for materials with RIRs of  $\sim 1.0$  if short scan ranges and long count times are employed. Clearly, it is straightforward to achieve detection limits less than 1 wt% with routine data collection parameters for materials whose reflections are not completely overlapped by stronger adjacent reflections.

### Safety Considerations

The careful, alert, and informed worker need to feel no hesitancy whatsoever in operating X-ray diffraction equipment, but the use of such equipment by careless or uninformed persons is dangerous. The hazards involved come from two sources, the X-rays themselves and the high voltages used to generate them. Workers must never, knowingly or otherwise, expose themselves to direct or secondary radiation. The effects of exposure to X-radiation are cumulative, and may lead to serious and permanent injury. The voltages normally used in X-ray diffraction lie in the range 25–55 kV, and, needless to say, all contact with equipment at such potentials must be avoided.

X-ray installations must be controlled periodically with Geiger counters and personnel must wear badges and have periodical blood analysis.

### Acknowledgments

### Introduction

To ‘look’ inside a crystal, the wavelength of the incident beam must be of the same order of magnitude as the distance between the units of the crystal ( $\sim 1 \text{ \AA}$ ). X-rays, in the wavelength range  $0.7\text{--}2.0 \text{ \AA}$ , are the ideal radiation and provide a powerful tool for investigating crystal structures and obtaining an image of objects (molecules, ions, etc.) with atomic dimensions.

The electric field of X-rays exert forces on electrons of atoms, and they are accelerated. In terms of a classical model, an accelerated charge radiates, and this radiation has the same frequency as the primary beam, but  $\pi$  out of phase with it, and it is called scattered radiation.

After constructive interference, this radiation produces experimental intensities, and from these experimental magnitudes the structure factor modulus,  $|F(hkl)|$ , is obtained. A Fourier analysis based on structure factors and a calculated set of phases determines with precision the atomic arrangement in space and provides an image of the internal structure of the crystal.

Nowadays, very complex molecules can be investigated; and the structures of proteins, enzymes, nucleic acids, and even viruses are being revealed by new powerful X-ray diffraction techniques.

On the other hand, new models for the electron density, application of topological analysis techniques, and use of synchrotron radiation allow us a quantitative study of several molecular properties in crystalline solids.

### Concepts of Crystallography

A crystal may be defined as a homogeneous solid in which a motif, made of molecules or groups of molecules (or ions, for inorganic crystals) with a definite chemical composition, shows a regular repetition in three-dimensional space and is bounded by plane faces.

Every crystal has a lattice as its geometrical basis. A lattice may be described as a regular, infinite arrangement of points (or motifs) in which every point has the same environment as any other point; the motif is repeated periodically at intervals  $a$ ,  $b$ , and  $c$  along three noncoplanar basic vectors  $a$ ,  $b$ , and  $c$ .

Any point in the lattice may be chosen as an origin, and the position of any other point of the lattice is defined uniquely by the vector:

$$\mathbf{t} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c} \quad [1]$$

where  $u$ ,  $v$ , and  $w$  are positive or negative integers or zero (in some cases, they can have rational values). The three basis vectors ( $a$ ,  $b$ , and  $c$ ) define a parallelepiped, known as the unit cell (the smallest three-dimensional volume element from which the crystal can be constructed). If the cell is primitive, then  $u$ ,  $v$ , and  $w$  in eqn [1] are integers, but if the cell is multiple, then  $u$ ,  $v$ , and  $w$  will have rational values.

The directions of the vectors  $a$ ,  $b$ , and  $c$  are the three axes of the unit cell (indicated by ‘ $a$ ’, ‘ $b$ ’, and ‘ $c$ ’), and the angles between them are indicated by ‘ $\alpha$ ’, ‘ $\beta$ ’, and ‘ $\gamma$ ’ (Figure 1). The values of these six parameters define the type of cell, and so  $a \neq b \neq c$  and  $\alpha \neq \beta \neq \gamma$  is triclinic;  $a \neq b \neq c$  and  $\alpha = \gamma = 90^\circ$ ,  $\beta \neq 90^\circ$  is monoclinic;  $a \neq b \neq c$  and  $\alpha = \beta = \gamma = 90^\circ$  is orthorhombic;  $a = b \neq c$  and  $\alpha = \beta = \gamma = 90^\circ$  is tetragonal;  $a = b = c$  and  $\alpha = \beta = \gamma \neq 90^\circ$  is trigonal;  $a = b = c$  and  $\alpha = \beta = \gamma = 90^\circ$  is cubic;  $a = b \neq c$  and  $\alpha = \beta = 90^\circ$ ,  $\gamma = 120^\circ$  are hexagonal. Considering primitive and

### Introduction

To ‘look’ inside a crystal, the wavelength of the incident beam must be of the same order of magnitude as the distance between the units of the crystal ( $\sim 1 \text{ \AA}$ ). X-rays, in the wavelength range  $0.7\text{--}2.0 \text{ \AA}$ , are the ideal radiation and provide a powerful tool for investigating crystal structures and obtaining an image of objects (molecules, ions, etc.) with atomic dimensions.

The electric field of X-rays exert forces on electrons of atoms, and they are accelerated. In terms of a classical model, an accelerated charge radiates, and this radiation has the same frequency as the primary beam, but  $\pi$  out of phase with it, and it is called scattered radiation.

After constructive interference, this radiation produces experimental intensities, and from these experimental magnitudes the structure factor modulus,  $|F(hkl)|$ , is obtained. A Fourier analysis based on structure factors and a calculated set of phases determines with precision the atomic arrangement in space and provides an image of the internal structure of the crystal.

Nowadays, very complex molecules can be investigated; and the structures of proteins, enzymes, nucleic acids, and even viruses are being revealed by new powerful X-ray diffraction techniques.

On the other hand, new models for the electron density, application of topological analysis techniques, and use of synchrotron radiation allow us a quantitative study of several molecular properties in crystalline solids.

### Concepts of Crystallography

A crystal may be defined as a homogeneous solid in which a motif, made of molecules or groups of molecules (or ions, for inorganic crystals) with a definite chemical composition, shows a regular repetition in three-dimensional space and is bounded by plane faces.

Every crystal has a lattice as its geometrical basis. A lattice may be described as a regular, infinite arrangement of points (or motifs) in which every point has the same environment as any other point; the motif is repeated periodically at intervals  $a$ ,  $b$ , and  $c$  along three noncoplanar basic vectors  $a$ ,  $b$ , and  $c$ .

Any point in the lattice may be chosen as an origin, and the position of any other point of the lattice is defined uniquely by the vector:

$$\mathbf{t} = u\mathbf{a} + v\mathbf{b} + w\mathbf{c} \quad [1]$$

where  $u$ ,  $v$ , and  $w$  are positive or negative integers or zero (in some cases, they can have rational values). The three basis vectors ( $a$ ,  $b$ , and  $c$ ) define a parallelepiped, known as the unit cell (the smallest three-dimensional volume element from which the crystal can be constructed). If the cell is primitive, then  $u$ ,  $v$ , and  $w$  in eqn [1] are integers, but if the cell is multiple, then  $u$ ,  $v$ , and  $w$  will have rational values.

The directions of the vectors  $a$ ,  $b$ , and  $c$  are the three axes of the unit cell (indicated by ‘ $a$ ’, ‘ $b$ ’, and ‘ $c$ ’), and the angles between them are indicated by ‘ $\alpha$ ’, ‘ $\beta$ ’, and ‘ $\gamma$ ’ (Figure 1). The values of these six parameters define the type of cell, and so  $a \neq b \neq c$  and  $\alpha \neq \beta \neq \gamma$  is triclinic;  $a \neq b \neq c$  and  $\alpha = \gamma = 90^\circ$ ,  $\beta \neq 90^\circ$  is monoclinic;  $a \neq b \neq c$  and  $\alpha = \beta = \gamma = 90^\circ$  is orthorhombic;  $a = b \neq c$  and  $\alpha = \beta = \gamma = 90^\circ$  is tetragonal;  $a = b = c$  and  $\alpha = \beta = \gamma \neq 90^\circ$  is trigonal;  $a = b = c$  and  $\alpha = \beta = \gamma = 90^\circ$  is cubic;  $a = b \neq c$  and  $\alpha = \beta = 90^\circ$ ,  $\gamma = 120^\circ$  are hexagonal. Considering primitive and

**Figure 1** Representation of a general unit cell, introducing the notation.

nonprimitive cells (centered on a pair of opposite faces, *C* (*A*, *B*); body-centered *I*; and centered on all faces, *F*), we obtain the 14 possible space lattices called Bravais lattices (Auguste Bravais first listed them in 1850): triclinic *P*, monoclinic *P*, *C*, orthorhombic *P*, *C*, *I*, *F*, tetragonal *P*, *I*, cubic *P*, *I*, *F*, hexagonal *P* and trigonal *P* (*R*, described with ‘hexagonal axes’).

In 1912 M. Von Laue suggested that a crystal could act as a three-dimensional diffraction grating for X-rays with a wavelength comparable with interatomic distances, and in the same year W.L. Bragg described a simple method for obtaining the conditions for diffraction. His interpretation, although an oversimplification, gives a clear representation of the features of the complete process. In the crystal, all scatterers (the motif) forming a three-dimensional array would fall on sets of equispaced planes. Bragg considered that each of these planes would act as a partial reflector of X-rays.

Let *AB* be an incident beam corresponding to a plane wavefront (with  $\lambda$  wavelength), and let  $\theta$  be the angle between this incident beam and the family of planes with interplanar spacing *d*. From **Figure 2** it is clear that a difference exists in the path crossed between the waves scattered at the points *A*<sub>1</sub> and *A*<sub>2</sub> that is equal to  $BA_2 + A_2C = 2d \sin \theta$  ( $BA_2 = A_2C$  and  $\sin \theta = BA_2/d$ ). The two waves will combine with maximum positive interference (will be in phase) if this difference in the path is a multiple of  $\lambda$ :

$$2d \sin \theta = n\lambda \quad [2]$$

Equation [2] is known as the Bragg law and it gives an angle of reflection  $\theta$  in terms of the interplanar spacing, *d*, and the X-ray wavelength  $\lambda$ .

A more realistic treatment, considering the diffraction from a net of scattering centers, gives rise to the conditions known as the Laue equations. These two approaches to X-ray scattering by crystals can be shown to be equivalent.

**Figure 2** Simple scheme of the Bragg reflection process, showing the parallel waves being in phase after reflection and how the path difference equals  $2d \sin \theta$ .

## The Reciprocal Lattice

For each direct lattice, a corresponding reciprocal lattice can be postulated. It has the same symmetry as the direct lattice and may be derived from it both mathematically and graphically. This concept was introduced by P. Ewald in 1921. The parameters are designed as  $a^*$ ,  $b^*$ , and  $c^*$ . By definition they are perpendicular to the planes defined by ‘*bc*’, ‘*ac*’, and ‘*ab*’, respectively, and satisfy the following two conditions:

$$a^* \cdot b = a^* \cdot c = b^* \cdot a = b^* \cdot c = c^* \cdot a = c^* \cdot b = 0$$

$$a^* \cdot a = b^* \cdot b = c^* \cdot c = 1.$$

Also, the volume of the reciprocal lattice is  $V^* = V^{-1}$ . Accordingly,  $a^*$ ,  $b^*$ , and  $c^*$  may be written as

$$a^* = (b \wedge c)/V; \quad b^* = (c \wedge a)/V; \quad c^* = (a \wedge b)/V$$

or, in moduli,

$$a^* = (bc \sin \alpha)/V;$$

$$b^* = (ca \sin \beta)/V;$$

$$c^* = (ab \sin \gamma)/V.$$

Mathematically, it is more convenient to use the reciprocal lattice since any family of planes in the direct lattice is represented by a point or node in the reciprocal space.

## Miller Indices

The important role that crystallographic planes play in the diffraction process, being necessary to define properly each crystallographic plane, has been shown. Given the crystallographic axes ‘*a*’, ‘*b*’, and ‘*c*’, a plane can be defined by three integers. This notation was introduced first by Miller in 1839, and the integers *h*, *k*, and *l* are called Miller indices. The

**Figure 3** Intercepts of the plane  $Q$ , in three-dimensional space, on the crystallographic axes at lengths  $a/h$ ,  $b/k$ , and  $c/l$ .

plane intersects the three crystallographic axes at lengths  $a/h$ ,  $b/k$ , and  $c/l$ , dividing the crystallographic axes in  $h$ ,  $k$ , and  $l$  parts, respectively. For instance, for the plane  $Q$  in **Figure 3**,  $a/h = a/3$ ,  $b/k = b/4$ , and  $c/l = c/2$ , and the Miller indices for  $Q$  are (342).

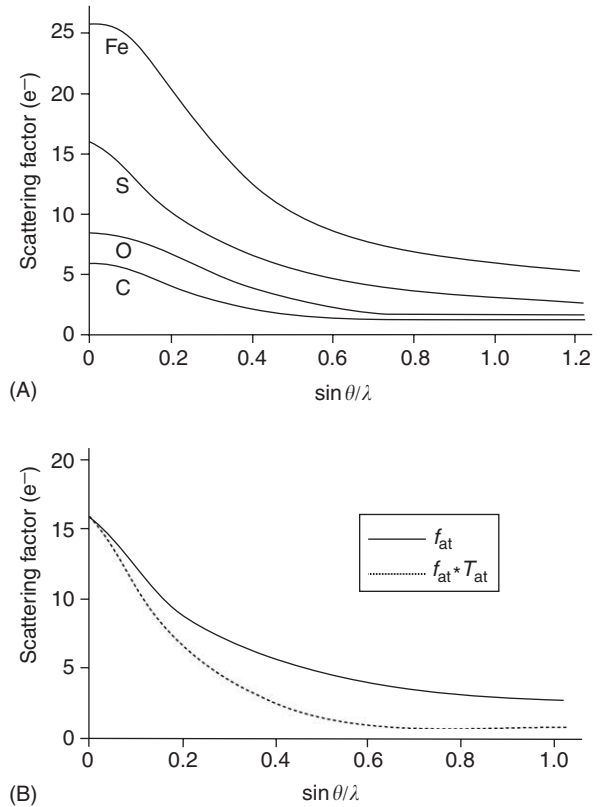

If a plane is parallel to a crystallographic axis, the spacing in that direction will be  $\infty$ , and therefore the Miller index will be 0. The crystallographic planes parallel to one axis are defined by  $(0kl)$ ,  $(b0l)$ , and  $(hk0)$ , respectively. Planes parallel to faces A, B, and C of the unit cell will be  $(h00)$ ,  $(0k0)$ , and  $(00l)$ , respectively.

This notation for the crystallographic planes will be used later in the description of the structure factor.

## Scattering Factor and Structure Factor

The total scattering of the unit cell will be the result of the amplitude of the waves scattered by the electrons of every individual atom. The total electron density of an atom can be regarded as a spherically symmetric region of charge around the nucleus. This distribution is defined by  $\rho(r)$ , the electron density at distance  $r$  from the nucleus.

The Fourier transform of  $\rho(r)$  is called the atomic scattering factor and is denoted by  $f_{\text{at}}$ . It represents the amplitude of scattering expressed in units of the scattering of a single point electron at the

**Figure 4** (A) Atomic scattering factors,  $f_{\text{at}}$ , as a function of  $\sin \theta/\lambda$  for different neutral atoms, showing how  $f_{\text{at}} = Z$  at  $\sin \theta/\lambda = 0.0$ . (B) Influence of the thermal vibration on the atomic scattering factor.

origin:

$$f_{\text{at}} = \int_{\text{all space}} \rho(r) \exp(2\pi i \mathbf{r} \cdot \mathbf{s}) dV \quad [3]$$

where  $\mathbf{s}$  is called the scattering vector, with  $s = 2 \sin \theta/\lambda$ . The electron density,  $\rho(r)$ , is known for practically all neutral atoms and ions from quantum mechanical calculations, via Hartree–Fock methods for lighter atoms and via the Thomas–Fermi approximation for heavier atoms, with high accuracy. The scattering factors are tabulated as a function of  $\sin \theta/\lambda$  in the *International Tables for Crystallography*.

The atomic scattering factor depends on several factors: the nature of the atom, the wavelength of the incident radiation, the scattering direction, and the thermal vibrations of the atom. **Figure 4A** shows how  $f_{\text{at}}$  behaves with  $\sin \theta/\lambda$ , being  $Z$  (the atomic number) at  $\sin \theta/\lambda = 0$ , decreasing at higher values of  $\sin \theta/\lambda$ .

The thermal vibrations produce a more diffused distribution of the electron density than does a stationary model, increasing the atomic effective volume, making the interference within the atom more noticeable, and making consequently the decrease in the atomic scattering factor more rapid (see **Figure 4B**).

Assuming an isotropic model for thermal vibrations, the temperature correction factor for an atom is

$$T_j = \exp[B_j(\sin^2 \theta)/\lambda^2] \quad [4]$$

$B_j$  is usually known as the atomic temperature factor, given by  $B_j = 8\pi^2 U_j^2$  ( $\text{\AA}^2$ ), where  $U_j^2$  is the vibration mean-square amplitude of the atom.

The temperature-corrected atomic scattering factor will be

$$f_j = f_{at,j} \cdot T_j \quad [5]$$

The structure factor,  $F(hkl)$ , which expresses the combined scattering of X-rays for all atoms in the unit cell for the reflection  $(hkl)$

$$F(hkl) = \sum_{j=1}^N f_j \exp\{2\pi i(hx_j + ky_j + lz_j)\} \quad [6]$$

where  $N$  is the number of atoms in the unit cell,  $f_j$  is the atomic scattering factor of the  $j$ th atom (including the temperature factor correction), and  $x_j$ ,  $y_j$ , and  $z_j$  are fractional coordinates ( $x_j = x/a$ ;  $y_j = y/b$ ;  $z_j = z/c$ ).

In the general case, the structure factor has a complex magnitude, and we may write

$$f(hkl) = |F(hkl)|e^{i\Phi(hkl)} \quad [7]$$

where  $|F(hkl)|$  is the structure amplitude and  $\Phi(hkl)$  the phase of the reflection.

In an X-ray diffraction experiment, the intensity of every reflection may be measured by integrating the peak over a suitable angular range around the ideal Bragg angle (a 'real' crystal has defects and mosaic structure, and there exist lattice distortions). This experimental intensity,  $I_{(hkl)}$ , with certain necessary corrections, is directly related to the structure through the structure amplitude,  $|F(hkl)|$ ,

$$I_{(hkl)} = k_1 k_2 I_0 LPTE |F(hkl)|^2 \quad [8]$$

where

$I_0$ : intensity of the incident beam

$k_1$ : collects three universal constants,  $e^4/m^2c^4$

$k_2$ : is a constant for a given diffraction experiment,  $\lambda^3 \Omega/V^2$  ( $\Omega$  is the volume of the crystal and  $V$  is the volume of the unit cell)

$L$ : is the Lorentz factor. Depends on the diffraction technique and is related to the different times-of-reflection opportunity of the different points of the reciprocal lattice. It is a simple function of  $\theta$ , as  $L = (\sin 2\theta)^{-1}$ .

$P$ : is the polarization factor. Depends on the Bragg angle and takes into account the polarization of the X-ray beam after the scattering process. Also a function of  $\theta$ , as  $P = (1 + \cos^2 2\theta)/2$ . Additional

polarization correction may be applied to the monochromator.

$T$ : is the transmission factor. Depends on the capacity of the crystal to absorb the X-rays. Is possible to correct for absorption if the shape of the crystal is known. Since an accurate description of the crystal is very difficult to obtain, the absorption remains one of the most serious (if not the most) sources of error in the experimental determination of intensities.

$E$ : is the extinction coefficient. It depends on the mosaic structure of the crystal and has two components. The secondary extinction (the most important) takes into account that a fraction of the incident beam is reflected by the planes. The primary extinction takes into account the loss of intensity due to multiple reflections from different lattice planes.

## Experimental Structure Factors and Intensities

The structure factor plays a very important role in the determination of the crystal structure because it is the only factor that gives us information about the atomic positions. The main problem in a structure analysis is just the inability to fully determine in an X-ray diffraction experiment the structure factor.

Although the structure factor modulus (structure amplitude) can be obtained from the intensity data (eqn [8]), the corresponding phase cannot be measured directly experimentally. The amplitude values alone cannot be used to determine directly the atomic positions. Incorrect phase values will lead to an incorrect calculated electron density and an erroneous final structure. This is referred to as the phase problem in crystallography and is the central problem in X-ray structure analysis.

Despite this 'limitation', the structure factor amplitude, without knowledge of the phases, has several applications in preliminary structure analysis.

The experimental diffraction pattern has to be described with the proper cell parameters to assign the correct  $hkl$  indices to each observed reflection. This process is called indexing, and essentially it is achieved by solving the following quadratic equation:

$$\begin{aligned} (1/d_{hkl})^2 &= (2 \sin \theta / \lambda)^2 = h^2 a^{*2} + k^2 b^{*2} + l^2 c^{*2} \\ &\quad + 2hka^*b^* \cos \gamma^* + 2klb^*c^* \cos \alpha^* \\ &\quad + 2lhc^*a^* \cos \beta^* \end{aligned} \quad [9]$$

where  $h$ ,  $k$ , and  $l$  must be integers.

**Table 1** Limiting conditions for screw-axes

Screw-axis	Limiting conditions	Orientation	Translation
$2_1$	$h00: h=2n$	$\parallel a$	$a/2$
$2_1$	$0k0: k=2n$	$\parallel b$	$b/2$
$2_1$	$00l: l=2n$	$\parallel c$	$c/2$
$4_1$ or $4_3$	$00l: l=4n$	$\parallel c$	$c/4, 3c/4$

**Table 2** Limiting conditions for glide-planes

Glide-plane	Limiting conditions	Orientation	Translation
$a$	$h0l: h=2n$		$a/2$
$a$	$hk0: h=2n$	$\perp b$	$a/2$
$b$	$0kl: k=2n$	$\perp c$	$b/2$
$c$	$h0l: l=2n$	$\perp b$	$c/2$
$n$	$0kl: k+l=2n$	$\perp a$	$b/2 + c/2$

The experimental X-ray diffraction pattern allows us also to determine the unit cell type. With the help of systematic absences, the unit cell centering may be assigned and the cell classified as primitive, (*P* type), side-centered (*A*, *B*, or *C* type), face-centered (*F* type), or body-centered (*I* type).

No systematic absences are present for a primitive unit cell. The indices are unmixed (all indices odd or all even; otherwise is called 'mixed') for a side-centered unit cell; showing only the  $k+l=2n$  reflections for the *A* type;  $h+l=2n$  for *B*; and  $h+k=2n$  for *C*. All reflections with mixed indices are missing in a face-centered unit cell, while for a body-centered unit cell all  $h+k+l=\text{odd}$  reflections are missing.

The diffraction pattern can also reveal translation-symmetry elements by considering the systematic absences. These elements are the screw-axes (the action of a  $R_n$  screw axis along the '*a*' direction is a rotation  $2\pi/R$  followed by a translation  $(n/R) \cdot a$ ) and the glide planes (a combination of reflection and translation). **Tables 1** and **2** show the limiting conditions for some screw-axes and glide-planes. Full information on crystallographic symmetry groups is compiled in the *International Tables for Crystallography*, vol. A.

Using this information, the proper space group may be assigned to the experimental data, although the existence of a symmetry centre may remain uncertain in some cases.

## Electron Density and the Phase Problem

The electron density function,  $\rho(r)$  (measured in  $e^- \text{\AA}^{-3}$ ), allows us to know the molecular structure

**Figure 5** Projection of the electron density contour map for benzene on the plane of the molecule. The positive and zero isocontours are represented by solid and dashed lines, respectively.

from which a crystal is made; the electron density is concentrated in the vicinity of the nucleus, showing peaks at the electron density maxima (atomic positions) and taking relatively low values out of the atomic positions.

The electron density is usually computed by Fourier synthesis at the points (*x*, *y*, *z*) of a three-dimensional grid. A grid spacing of  $\sim 0.2\text{--}0.4 \text{\AA}$  in the three directions is satisfactory for most electron density maps.

In order to facilitate interpretation of these three-dimensional maps, the electron density is presented in sections (with a constant value of *x*, *y*, or *z*) that may be contoured by lines passing through points of equal electron density. For illustration, **Figure 5** shows the features of a typical two-dimensional electron density map. To a first approximation, the heights of the peaks are proportional to the atomic number.

The process of finding the electron density is not straightforward. This function can be expressed as a three-dimensional Fourier series,

$$\rho(x, y, z) = \frac{1}{V_{\text{cell}}} \sum_h \sum_k \sum_l F(hkl) e^{-2\pi i(hx + ky + lz)} \quad [10]$$

where  $F(hkl)$  is the structure factor, as was shown in eqns [6] and [7]. The number of reflections used in practice in this expression is over several thousands for the small unit cells typical of common organic/inorganic compounds.

Alternative expressions, considering the Friedel's law ( $|F(hkl)| = |F(-h - k - l)|$ ) and the definition of

complex function, lead to

$$\rho(x, y, z) = \frac{2}{V_{\text{cell}}} \sum_{h=0} \sum_k \sum_l |F(hkl)| \times \cos[2\pi(hx + ky + lz) - \Phi(hkl)] \quad [11]$$

that shows clearly the dependence of  $\rho(x, y, z)$  on the phase  $\Phi(hkl)$ . This is the essence of the crystallographic problem referred to as the phase problem in crystallography: in eqn [11] the values of the moduli  $|F(hkl)|$  can be obtained immediately from the observed intensities (according to eqn [8]), but the phase information is lost in the experiment and cannot be found directly from the experimental data.

However it is possible in general to solve the phase problem; because the number of equations is greater than the number of unknowns, the system is said to be overdetermined.

## Jumping the Phase Problem to Solve the Crystal Structure

In order to solve the structure (have a model of the structure to be refined), methods of extracting phase information are needed, for which the set of  $|F_0(hkl)|$  data (subscript o means ‘observed’ or ‘experimental’) constitute the starting point for the methods of structure analysis.

A general solution to the phase problem has not been found yet, but there are several methods that can be applied successfully. They all need a considerable amount of computation, but with modern computers and software, this process is relatively easily performed. There are two classical approaches to solving the phase problem.

### Patterson Methods

Based on the three-dimensional function proposed by Patterson in 1934, a new Fourier series that could be calculated directly from the measured intensities. This function is defined as the self-convolution of the electron density,  $\rho(r)$ , and has the same periodicity as the electron density:

$$P(u, v, w) = \frac{2}{V_{\text{cell}}} \sum_h \sum_k \sum_l |F(hkl)|^2 \times \cos[2\pi(hu + kv + lw)] \quad [12]$$

The Patterson function gives information about interatomic vectors (distances) in the structure. The height of each peak is proportional to the product of the atomic numbers of the two atoms connected ( $Z_i, Z_j$ ) multiplied by the multiplicity of the vector.

Patterson methods are specially oriented to solving structures containing heavy atoms, where it becomes easy to derive the projected positions of the heavy atoms, and their coordinates represent a good initial model for solving the structure. The calculated phases,  $\Phi_c(hkl)$ , are a good approximation of the true phase for calculating an electron density map by means of eqn [11], using the observed amplitudes,  $|F_0(hkl)|$ , and the calculated phases to find new atomic positions and proceed by successive Fourier cycles until the structure is completed.

Nowadays, procedures for the automatic localization of the heavy atom positions from the Patterson function have been developed both for small molecules and for biological macromolecules.

Alternative ways of exploiting the information in a Patterson map are known as molecular replacement methods, being able to locate structural fragments and using this initial phase information to proceed as in the case of heavy atoms.

All these procedures are nicely implemented in fully automated packages such as DirDif, SHELXS97, or AMORE (for proteins).

### Direct Methods

This term is used to indicate those methods that try to determine the values of the structure factor phases *ab initio* from the amplitudes of the structure factors through mathematical relationships. Particularly useful is their ability to yield good phase information for structures without heavy atoms.

The first mathematical relationships were obtained, starting about 1950, between the sign of phases in centrosymmetric structures in the form of inequalities, later extended to noncentrosymmetric structures, using unitary structure factors.

$$U(hkl) = F(hkl) / \sum_{j=1}^N f_j \quad [13]$$

The inequalities have limited practical interest because it requires very large values of  $|U(hkl)|$  to give useful information for solving a structure.

It was in 1953 that Hauptman and Karle established the basic concepts and the probabilistic foundations of direct methods. Of major importance was the introduction of the normalized structure factor, given by the equation

$$E(hkl) = F(hkl) / (\varepsilon \Sigma)^{1/2} \quad \text{with} \quad \Sigma = \sum_{j=1}^N f_j^2 \quad [14]$$

where  $\Sigma$  represents the average value of  $|F|^2$  for the scattering angle corresponding to  $(hkl)$ , and  $\varepsilon$  the enhancement factor, depending on the space group and the reflection itself.

**Figure 6** Probability distributions of  $|E(hkl)|$  for noncentrosymmetric (---) and centrosymmetric (—) structures.

The structure factor,  $E(hkl)$  (and  $U(hkl)$ ), is independent of the scattering angle,  $\theta$ . This is very important in the application of direct methods since high-order reflections with small  $|F(hkl)|$  values can have quite large  $|F(hkl)|$  values.

Other theoretical advantage of the structure factor  $E(hkl)$  is that the distribution of  $|F(hkl)|$  depends only on the space group and not on the complexity of the structure; in this way the form of its probability distributions shows the presence of an inversion center in the crystal (centric distribution) or not (acentric distribution), see **Figure 6**.

In general, the direct methods require initially a few reflections with phases known, either uniquely or symbolically. Some basic features of direct methods are shown briefly below; a detailed description of procedures and applications is beyond the scope of this article and can be found in the work listed in the further reading section.

Structure invariants are quantities independent of the chosen reference system, their value depending only on the structure. The product  $E(h_1k_1l_1)E(h_2k_2l_2) \dots E(h_nk_nl_n) = |E(h_1k_1l_1)E(h_2k_2l_2) \dots E(h_nk_nl_n)| \exp[i(\Phi_1\Phi_2 \dots \Phi_n)]$  is a structure invariant when  $(h_1k_1l_1) + (h_2k_2l_2) + \dots + (h_nk_nl_n) = 0$ .

The most important structure invariants are the triplet invariants, represented by  $[F(-h_1 - k_1 - l_1)F(h_2k_2l_2)F(h_1 - h_2k_1 - k_2l_1 - l_2)]$ , and the quartet invariants  $[F(-h_1 - k_1 - l_1)F(h_2k_2l_2)F(h_3k_3l_3)F(h_1 - h_2 - h_3k_1 - k_2 - k_3l_1 - l_2 - l_3)]$ . The terms ‘triplet’ and ‘quartet’ refer to the sums of the phases since the moduli are origin independent.

The structure semi-invariants are single phases, or linear combinations of phases, which are invariant only for a permitted change of origin. The origin

is restricted in the cell to the sites with the same point symmetry (called permissible origins). A semi-invariant can be transformed into an invariant by adding one or more pairs of symmetry-equivalent phases.

Probability methods are applied to the estimation of the reliability of the relationships between the phases and magnitudes, and their use has proved to be the most important approach in the practical use of direct methods.

The tangent formula provides a powerful equation for establishing relations between structure factors and phases and for refining a probabilistic set of phases till self-consistence: this process is usually known as convergence. With the knowledge of a sufficiently large subset of phases, an electron density map can be calculated using eqn [11] to reveal the structure. These maps are called  $E$ -maps because they use the normalized structure factor,  $E(hkl)$ , as coefficients of the Fourier series rather than the structure factor,  $F(hkl)$ .

Direct methods may be automatically applied using program packages like SIR2004.

## Completing and Refining the Structure

Frequently the initial set of phases produces incomplete structural models. These models have to be completed and refined to obtain the final crystal structure.

The complete structure may be obtained using the difference Fourier synthesis method, based on the difference between the electron density observed,  $\rho_o(x, y, z)$ , and the electron density calculated,  $\rho_c(x, y, z)$ .

$$\Delta\rho(x, y, z) = \rho_o(x, y, z) - \rho_c(x, y, z) \quad [15]$$

with both magnitudes calculated as in eqn [10], but the values of  $\Phi_o$  are unknown, making it necessary to make the approximation  $\Phi_o \approx \Phi_c$ . The electron density difference then becomes

$$\Delta\rho(x, y, z) = \frac{1}{V_{\text{cell}}} \sum_b \sum_k \sum_l (|F_o(hkl)| - |F_c(hkl)|) \exp[-2\pi i(hx + ky + lz) + i\phi_c(hkl)] \quad [16]$$

If the structural model is incomplete, the missing atomic positions appear as positive maxima in a difference Fourier synthesis ( $\Delta\rho$ ).

For refining the structure, the most widely used method is the least-squares method. In essence, the process consists of adjusting a series of parameters

defining the structural model to minimize the difference between the experimental values,  $|F_o(hkl)|$ , and the calculated values,  $|F_c(hkl)|$ , derived from the structure model. Among these parameters are the overall scale factor, the coordinates for each atom, and their isotropic or anisotropic thermal parameters.

The refinement is carried out using  $F^2$  instead of  $F(hkl)$  for all independent measured reflections. This refinement process requires several cycles until convergence is reached to conclude, as a final step, by computing a difference Fourier synthesis in order to locate the hydrogen atoms. Sometimes, when H atoms are difficult to locate, it is possible to assign geometrically calculated positions for the missing hydrogen atoms.

The most widely used measure of convergence is the residual index or  $R$ -factor, expressing the disagreement between the  $|F_o(hkl)|$  and the  $|F_c(hkl)|$  values. The most common  $R$ -indices are based on  $F^2$  and  $F$ .

$$wR2 = \left\{ \sum_{hkl} [w(F_o^2 - F_c^2)]^2 / \sum_{hkl} w(F_o^2)^2 \right\}^{1/2} \quad [17]$$

$$R1 = \sum_{hkl} (|F_o| - |F_c|) / \sum_{hkl} |F_o| \quad [18]$$

and the goodness of fit, always based on  $F^2$ .

$$\text{GOF} = S = \left\{ \sum_{hkl} [w(F_o^2 - F_c^2)]^2 / n - p \right\}^{1/2} \quad [19]$$

where  $w$  is a weighting scheme, important for associating a proper weight to each reflection;  $n$  is the number of reflections; and  $p$  is the total number of parameters refined. Low values of  $wR2$  ( $<15\%$ ),  $R1$  ( $<5\%$ ), and  $S$  ( $\sim 1.0$ ) are indications of the correctness of the crystal structure.

One complementary criterion of model quality during the refinement is the free- $R$  factor, which is computed with a small set of randomly chosen intensities, the test set, which are not used in the refinement.

The structural model used in general for the structural refinement assumes that the atoms are neutral and the electron density is spherically distributed about the atomic nuclei, with a radial dependence. This atomic model is adequate for structure determination but ignores the real effect of chemical bonding.

In the last three decades, a more flexible formalism was carried out, incorporating expansion and contraction of the atomic valence shell, variation of its

occupancy (loss of neutrality), and nonspherical density functions (multipolar spherical harmonic expansion).

This multipole refinement leads to a significant decrease in the residual indices and a reduction of features in the residual maps. Also, a topological study of the electron density described in this form allows us to obtain more quantitative information on electron distributions than can be derived from electron density maps, the bond order and its force, dipolar moments, covalent character, etc.

The limitations of the multipolar refinement are the exceptional demands it places on the X-ray data (in terms of quantity and quality) and the large number of additional parameters per atom that must be included in the least-squares refinement procedures. Nevertheless, charge density studies are becoming more and more popular due to the new experimental possibilities offered by the new area detectors and the more intense sources as provided by the synchrotrons.

The high-intensity, finely collimated polychromatic X-radiation from a synchrotron source can be used in a great variety of applications in modern crystallographic research.

## Macromolecular Crystallography

Macromolecular crystallography has had an extraordinary impact in the progress of major areas of research such as genomics and proteomics. The structure of proteins and other macromolecules of biological interest are best determined using X-ray crystallography.

Some of the so-called physical methods are among the most commonly applied in protein crystallography as the isomorphous replacement method and the anomalous scattering method.

The isomorphous replacement method is based on the experimental data sets of two or more structures differing only in the presence/absence of some atoms or in the presence of some atom of a different kind.

Such structures are called isomorphs, and the comparison of their intensity data can lead to a determination of their structures.

For proteins, the structures selected are the native protein and, in the most favorable cases, several isomorphous derivatives with different heavy atoms, every one bound at a certain site in the protein.

The structure factors are related as

$$|F_P| \exp(i\Phi_P) = |F_{PH}| \exp(i\Phi_{PH}) - F_H \quad [20]$$

where P stands for the native protein, PH for the heavy atom derivative, and H for the heavy atom.  $F_H$

can be determined using different sets of isomorphous derivatives; it is possible to obtain approximate phases capable of yielding interpretable electron density maps.

The anomalous scattering method uses the information provided by the anomalous signal. Anomalous scattering occurs when the frequency of the primary beam is close to the natural absorption frequency of some of the atoms in the structure. The anomalous signal is negligible for light atoms (C, N, O, ...) and only important when some heavy atoms are present.

In this case, the scattering factor is written in the form

$$f = f^o + f' + if'' \quad [21]$$

where  $f^o$  is the normal scattering, and  $f'$  and  $f''$  are the real and imaginary component corrections, respectively. The structure factor equation is made of three contributions taking the form

$$F(hkl) = F^o(hkl) + F'(hkl) + F''(hkl) \quad [22]$$

The most important consequence of this effect is the breaking of Friedel's law (the observation of the effects of the violation of Friedel's law is conditioned by the wavelength and the atoms in the crystal), and Friedel pairs are more correctly called Bijvoet pairs.

This breaking can be used to determine unambiguously the absolute configuration of the structure (in chiral crystals); calculating  $|F_c(hkl)|$  for a number of Friedel (Bijvoet) pairs, one of the enantiomorphs will fit better, and this will be the correct absolute configuration.

Using the anomalous scattering effect, we can locate heavy atom sites (very important in protein studies), and knowing their positions, it is possible to get phase information, although with the ambiguity

$$\Phi(hkl) = \Phi''(hkl) \pm \Delta\Phi(hkl) \quad [23]$$

$$|\Delta\Phi(hkl)| \approx \left| \cos^{-1} \left[ (|F^+| - |F^-|) / 2F'' \right] \right| \quad [24]$$

where  $F^+$  and  $F^-$  are structure factors of a Friedel pair.

The resolution of this equation leads to a solution of the structure. There are various ways of trying to solve this ambiguity, some of which are based on the use of a single wavelength (most protein crystals are sensitive to X-ray irradiation, and isomorphous derivatives are difficult to prepare), and others are based on a combination of different sources of information: (1) combining single isomorphous replacement and one-wavelength anomalous scattering; (2) introducing a second wavelength, generalized in recent years for

measuring data from the same species at different wavelengths, a technique called MAD (multiwavelength anomalous dispersion); (3) using algebraic methods based on simple rules that permit estimation of three-phase structure invariants; (4) using probability formulae integrating direct methods with one-wavelength anomalous scattering; (5) using Wang's method; (6) using direct methods; (7) resolving the phase ambiguity using Wilson statistics.

Finally, the other type of physical method, in an active state of development during the last few years, is that of multibeam reflection methods. These methods are based on the  $N$  beam diffraction effect ( $N > 1$ , integer), which occurs when  $N$  nodes of the reciprocal lattice diffract for a unique incident beam. These simultaneous reflections are very well known processes and can be treated in accordance with dynamic diffraction theory.

For instance, three-beam diffraction (one transmitted and two diffracted beams) is used for determination of triplet phases (see Direct Methods) and provides also a means of resolving the enantiomorphism problem without the need for anomalous scattering.

Experimentally,  $N$  beam diffraction can be achieved by rotating the crystal on a specially designed goniometer. This technique has been proved to be able to provide phase information for macromolecular crystals.

## Databases

There are three major databases storing all the crystal structures determined so far: the CSD (Cambridge Structural Database) contains all the organic and metal-organic compounds; the ICSD (Inorganic Crystal Structure Database) contains the inorganic compounds; and the PDB (Protein Data Bank) contains macromolecular structure data on proteins, nucleic acids, protein-nucleic acid complexes, and viruses.

The CSD, <http://www.ccdc.cam.ac.uk/>, contains more than 270 000 crystal structures determined using X-ray or neutron techniques. For each structure, the data stored include bibliographic information and experimental data, the chemical connectivity, and the crystal and molecular structures.

The ICSD, <http://www.fiz-informationsdienste.de/en/DB/icsd/index.html>, has complete structural information on more than 70 000 inorganic compounds.

The PDB, <http://www.rcsb.org/pdb/>, is freely available worldwide and stores sequence details, atomic coordinates, crystallization conditions, and three-dimensional structure and neighbors computed using various methods, derived geometric data, structure factors, and three-dimensional images.

## Instrumentation

Most of the single crystal structure determination experiments are based on the use of automated diffractometers.

Diffractometers are either used as laboratory instruments, based on the radiation produced by sealed or

rotating anode tubes and more recently in micro-sources, or as instruments set at the synchrotron sources. Apart from the X-ray source, the goniometer and detector are the fundamental parts of a diffractometer. A picture of a modern diffractometer is shown in **Figure 7**.

Nowadays most diffractometers use area detectors based on charge coupled device (CCD) technology (see **Figure 8**) although image plate devices are still used, particularly in macromolecular crystallography. Area detectors can collect a complete set of data in a few hours.

**Figure 7** One of the recently designed single crystal diffractometers equipped with a CCD detector and Kappa geometry. (Reproduced with permission from Brüker AXS.)

**Figure 8** View of one CCD detector. (Reproduced with permission from Brüker AXS.)

**Figure 9** The two most commonly used four-circle geometries, Kappa (A) and Euler (B). (Reproduced with permission from Brüker AXS.)

The present goniometers have been inspired by Euler or Kappa four circle geometries (see **Figure 9**) used in combination with point detectors; nevertheless the use of area detectors allows us to simplify the goniometer geometries by reducing the number of circles.

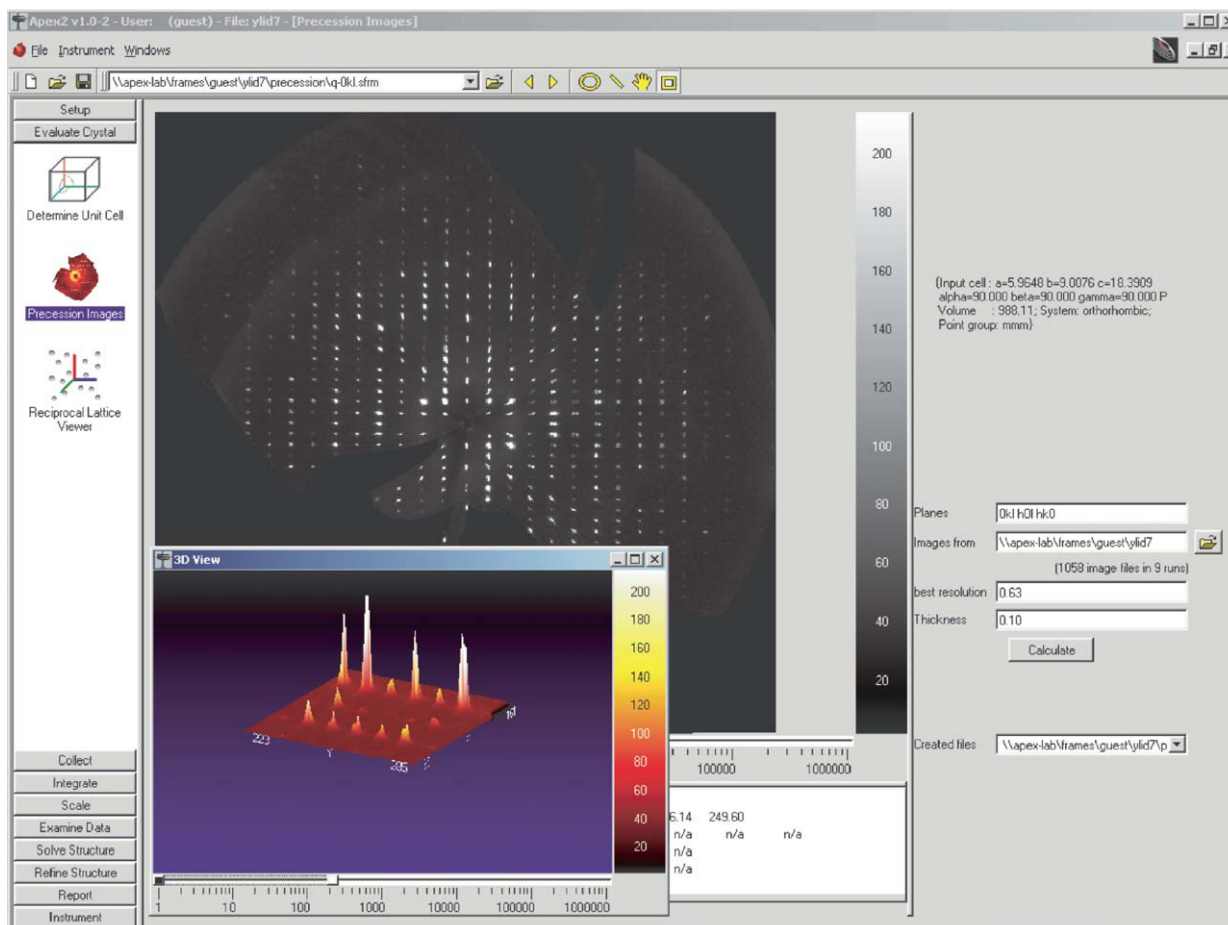

The output of an area detector is a set of frames containing a three-dimensional picture of the reciprocal space obtained by successive rotations of the crystal following a convenient, previously calculated strategy. **Figure 10** shows a frame as detected by a CCD for one small molecule/unit-cell.

The diffraction spots are integrated and scaled using automated procedures to get the intensities and structure factors necessary for solving and refining the crystal structure. **Figure 11** shows a screen of the computer when processing a collected set of data.

The advent of synchrotron radiation as a highly collimated and tunable source of X-rays has opened new prospects for the application of anomalous scattering. Several different data sets can be collected. In multiple-beam scattering methods, synchrotron radiation also offers advantages.

**Figure 10** Diffraction spots, for a small molecule/unit-cell, on a frame detected using a CCD.

**Figure 11** Computer screen showing the processing of a set of collected frames.

Tapping this X-ray source involves highly sophisticated technology tailored for particular applications, which include rapid data collection from unstable samples (e.g., proteins), poorly diffracting samples such as fibrous polymers or extremely small crystals, time-resolved studies of solid-state reactions or transformations including enzyme-catalyzed processes, and studying of crystals defects using X-ray topography.

## Safety

The specific hazards of analytical X-ray equipment can include exposure to an intense, localized primary X-ray beam, exposure to diffracted and/or scattered portions of the primary X-ray beam (includes X-ray leakage), and the high voltages used in generating the X-ray themselves.

There are three general principles of radiation protection: time, distance, and shielding. Decreasing the amount of time spent in the vicinity of the source of radiation, increasing the distance from a source of radiation, and increasing the amount of shielding around a source of radiation will decrease the amount of radiation exposure. Shielding for analytical X-ray units can range from the use of leaded glass to enclosures constructed of tin-impregnated polycarbonate.

The careful, alert, and informed worker need feel no hesitancy whatsoever in operating X-ray diffraction

equipment, but the use of such equipment by careless or uninformed persons is dangerous.

X-ray installations must be controlled periodically using Geiger counters, and personnel must wear badges and do periodical blood analysis.

### Introduction

X-ray fluorescence (XRF) spectrometry is an analytical technique used widely for elemental determinations in both industrial, and research and development laboratories. It belongs to a family of atomic spectrometry techniques but enjoys some distinctive analytical advantages compared with rival techniques, such as atomic absorption spectrometry (AAS) and inductively coupled plasma–atomic emission spectrometry (ICP–AES). XRF spectrometry is capable of determining almost all the elements in the periodic table, conventionally between sodium and uranium (including the electronegative elements, such as chlorine, phosphorus, sulfur, bromine, and iodine) to detection limits, often in the 1–10 mg kg<sup>−1</sup> range. Determinations can be extended down to boron, although at reduced sensitivity and with significant limitations in terms of the very small critical penetration depth of the corresponding fluorescence X-rays (see later). Unusually for an atomic spectrometry technique, samples are normally analyzed in solid (rather than solution) form, for example, as cast billets of metal, powdered material prepared as a pellet, or glass disks formed after fusion of the sample powder with a suitable flux. However, oils, liquors, brines, and other samples in the form of a liquid can also be analyzed directly, with minor modification to the analytical procedure (principally substituting a helium flush in the vacuum chamber). One important analytical characteristic of XRF is the inherently high precision of measurements that can be achieved in routine operation, generally superior to many other atomic spectrometry techniques other than those based on isotope dilution mass spectrometry. In comparison with ICP–mass spectrometry (MS), another multielement technique that is widely used for elemental determinations, XRF cannot match the low detection limits for the higher-atomic number elements, although ICP–MS itself suffers interferences on a number of lower-atomic number elements and cannot match the precision in their determination using XRF, so that in some routine applications XRF and ICP–MS are considered to be complementary techniques in laboratories undertaking comprehensive multielement analysis.

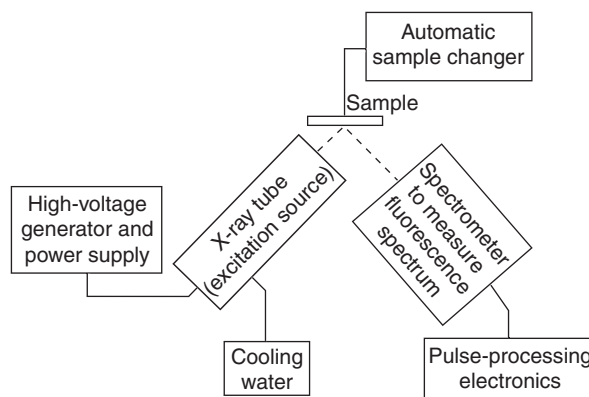

Taking account of its analytical capabilities, XRF has found widespread applications in the analysis of

cements, ceramics, refractories, iron, steel, nonferrous metals, plastics (for inorganic fillers), lubricating oils (for wear metals), fuel (for sulfur), geological samples, soils, sediments, air filters, archaeological, and forensic and biological samples. In addition, special forms of portable instrumentation have been developed for *in situ* measurements of contaminated soil, lead in paint, and alloy sorting (scrap metal recycling). *In vivo* assessment of lead in bone may be made using XRF as well as special forms of instrumentation for characterizing semiconductor materials. Because of the advantages XRF brings to these applications, XRF continues to play a dominant role in the relevant application laboratories.

### Forms of Instrumentation

Conventional XRF analyzers used for routine measurements in applications laboratories comprise an excitation source, sample presentation device, X-ray spectrometer, and associated control and signal-processing electronics (Figure 1). Two categories of instrumentation are available, one based on the use of wavelength dispersive (WD) spectrometers, the other on energy dispersive (ED) X-ray detectors. WD-XRF instruments are used widely for routine elemental analysis in production, quality control, and research laboratories, where speed of analysis and analytical precision are important requirements. Such instrumentation uses an X-ray tube as the excitation source and is available with one or two scanning goniometers (for sequential elemental analysis) or, alternatively, with a number of multiple fixed goniometer channels (for rapid simultaneous elemental detection).

ED-XRF instrumentation incorporating solid state semiconductor detectors offers different detection

**Figure 1** Schematic 'compartment' model of an XRF analyzer system showing the major instrumental components.

characteristics with parallel detection of the full X-ray spectrum. In addition to quantitative elemental analysis, such instrumentation offers unrivalled opportunities for rapid qualitative analysis, of value in forensic and alloy sorting applications, for example. Adequate excitation is provided by a lower-power X-ray tube arranged for direct or secondary target excitation, or alternatively a radioisotope excitation source may be used.

Despite these differences in analytical performance and operation, WD- and ED-XRF instrumentation are based on common principles, which are considered further in this section.

## Principles of Excitation

XRF involves the excitation of atoms in a sample using a source of X-ray photons, which are sufficiently energetic to cause ionization of inner-shell electrons. The resultant atoms are intrinsically unstable since they have a vacancy in an inner electron orbital and decay immediately to a more stable electronic state. This decay involves the transition of an electron from an outer orbital to fill this vacancy (Figure 2). As the electron falls down the potential energy gradient to an orbital closer to the nucleus, it loses energy by emitting an X-ray photon, so regaining a stable energetic configuration. The energy of

this photon is characteristic of the difference in energy between the two electronic states involved in the transition. Three analytically important series of X-ray lines can be emitted as a result of this excitation mechanism. These line series originate from the ionization of the K, L, or M orbitals. This excitation mechanism contrasts with that relevant to other atomic spectrometry techniques such as AAS and ICP-AES, which involve absorption and emission of radiation in the ultraviolet-visible region of the spectrum following the excitation of outer orbital electrons of atoms and ions.

## Line Series and Notations

Several alternative electronic transitions can occur following ionization of an inner-shell electron during the XRF process. For example, a vacancy created by ionization of a K-shell electron can be filled by transition of an electron from the L or M orbital level (Figure 2). The probability that an individual transition will occur (and, therefore, the relative intensity of the corresponding fluorescence line) is governed by quantum mechanical selection rules. Under the traditional Siegbahn notation, individual lines are identified using a convention based mainly on relative intensity, the two K-line transitions referred to above being identified as  $K\alpha$  and  $K\beta$  lines, respectively. To account for the fact that L and M orbital levels are not degenerate but are split in energy (an effect that becomes more significant with increased atomic number), corresponding fluorescence lines are subclassified. For example, the  $K\alpha$  line comprises two transitions,  $K\alpha_1$  and  $K\alpha_2$ , to describe the  $K-L_3$  and  $K-L_2$  transitions, both of which are permitted by selection rules. The principal fluorescence lines in the L and M spectra are identified in a similar manner, the more important lines being ( $L\alpha$ ,  $L\beta$ ,  $L\gamma$ ,  $L\eta$ ,  $M\alpha$ , and  $M\beta$ ). Although still widely used, this traditional notation has now been replaced by an International Union of Pure and Applied Chemistry (IUPAC) convention based on the rigorous use of spectroscopic terms. The  $K\alpha_1$  and  $K\alpha_2$  transitions are now denoted as  $K-L_3$  and  $K-L_2$  transitions, respectively, and the equivalence between the IUPAC and Siegbahn notations for other fluorescence lines is listed in Table 1.

One important aspect of XRF is the way in which the energy of each line series increases in a systematic manner with increasing atomic number of elements in the periodic table (Figure 3). This correlation results from the systematic increase in the potential energy of orbitals around an atom with increase in positive charge on the nucleus (and therefore with the atomic number of the element). This phenomenon

**Figure 2** Schematic mechanism of X-ray fluorescence. (A) Interaction of primary X-ray photon with electronic orbital of an atom causing ionization of a K-shell electron. (B) Deexcitation involving an electron transition from the L shell to the K shell accompanied by the emission of a  $K-L_{2,3}$  ( $K\alpha$ ) fluorescence X-ray. (C) Competitive mode of deexcitation involving an electron transition from the M shell to the K shell accompanied by the emission of a  $K-M_{2,3}$  ( $K\beta$ ) fluorescence X-ray. (D) Internal capture of a fluorescence X-ray leading to the emission of an Auger electron.

was incorporated in the laws propounded by Moseley at the beginning of the second decade of the twentieth century and was used to identify gaps in the periodic table corresponding to the existence of a number of undiscovered elements, including technetium, promethium, and rhenium. One consequence of this systematic variation is that the elemental interpretation of XRF spectra is particularly simple and the prediction of line overlap interferences relatively straightforward, especially when compared with the more complex spectra observed in optical emission techniques.

### Fluorescence Yield

The probability that a fluorescence X-ray will be emitted following ionization of an electron from a designated shell is quantified by a parameter called the fluorescence yield ( $\omega$ ). Values of the fluorescence yield (being the fraction of atoms that decay by yielding a fluorescence X-ray after ionization) for selected elements are listed in **Table 2**. The following general trends may be observed in these data. (1) Within a line series, fluorescence yields increase with atomic number. (2) The fluorescence yield of the line series of an individual element decreases in the order  $\omega_K > \omega_L > \omega_M$ , implying that, other factors being equal, the most sensitive determinations will be made from K-line emissions. (3) The fact that fluorescence yields are less than unity implies the existence of a competing deexcitation route for ionized atoms, which becomes increasingly important for the lighter elements. This competing route is the emission of Auger electrons, whereby the fluorescence X-ray is captured internally before it has escaped from the atom, causing the emission of secondary electrons

from outer orbitals (**Figure 2**). This signal forms the basis of a separate analytical technique (Auger spectroscopy) but in the context of XRF serves to reduce the sensitivity of fluorescence measurements.

### Line Selection for Analysis

In analytical applications, the most intense fluorescence line is selected normally for the determination of an element (to maximize sensitivity). Without further consideration, therefore, it might be expected that the appropriate K-L<sub>2,3</sub> (K $\alpha$ ) line would be used for all analytical measurements. However, account must also be taken of the variation in excitation efficiency and detection response of XRF instrumentation as a function of energy. In conventional XRF spectrometers, the upper limit for sensitive XRF measurements is between 20 and 30 keV, this limit being set by the maximum potential that can be applied to the X-ray tube. The lower limit for routine applications is  $\sim 1$  keV, this being set by the substantial increase in attenuation of X-ray photons of lower energy in the windows of X-ray detectors, noting that measurements at reduced sensitivity can be made down to  $\sim 0.2$  keV using more specialized spectrometer components. These instrumental limitations, therefore, dictate that the line selection for the determination of the elements between sodium and molybdenum would normally be the K-L<sub>2,3</sub> (K $\alpha$ ) line and for the elements barium to uranium, the L<sub>3</sub>-M<sub>4,5</sub> (L $\alpha$ ) line. A choice of K or L lines is available for the intermediate elements (ruthenium to barium), depending on the application and/or instrumentation. M lines would not be used normally for

**Figure 3** Systematic variation in the energy of K and L fluorescence emission lines with atomic number in the region 0–30 keV. The main sequence of K-lines for the elements carbon to tellurium is plotted, together with associated L-line emissions (iron–tellurium). Additional L-line emissions found in this region of the spectrum are plotted for convenience in two groups, iodine–lutetium and hafnium–uranium. Line heights correspond approximately to the relative intensities of emission lines, and for clarity, minor L-line emissions have been omitted.

analytical measurements using XRF because of potential spectral overlap problems, although they are used for the heaviest elements in electron microprobe applications.

## Mass Attenuation Effects

To be capable of inducing the ionization of electrons from a particular atomic orbital, X-ray photons from an excitation source must possess energy greater than a threshold value (the ionization energy of the line

series). X-ray photons below this energy threshold are incapable of exciting fluorescence for the line series. This property may be illustrated by examining the degree of attenuation of a monochromatic beam of X-rays as it traverses through a thin foil of an element (**Figure 4**). The degree of attenuation is given by the well known Beer's law,

$$I = I_0 \exp(-\mu x)$$

where  $I$  is the intensity of the transmitted beam,  $I_0$  the intensity of the incident beam,  $x$  the thickness of

Data abstracted from Colby JW (1968) *Advances in X-ray Analysis* 11: 287–305. The K-lines of the elements lanthanum–uranium are observed at energies above the normal analytical range limit of 30 keV.

the foil, and  $\mu$  the linear attenuation coefficient (which varies according to the composition of the foil and as a function of photon energy). In X-ray applications, it is normal to rearrange this expression as follows:

$$I = I_0 \exp ((-\mu/\rho)\rho x)$$

where  $\rho$  is the density and the term  $(\mu/\rho)$  is known as the mass attenuation coefficient. For composite materials, the bulk mass attenuation coefficient ( $\bar{\mu}$ ) may be calculated from the mass fractions of individual elemental components:

$$\bar{\mu} = \sum_i (\mu/p)_i - C_i$$

where  $C_i$  is the weight fraction of element  $i$  and the summation is undertaken over all elements ( $i$ ) present in the sample.

If the attenuation of an X-ray beam  $(\mu/p)$  through a thin foil of a specified element (taking iron and nickel as examples) is plotted as a function of photon energy (Figure 4), the intensity of the transmitted X-ray beam shows a sharp discontinuity called an absorption edge. This absorption edge corresponds to the energy threshold above which XRF phenomena are observed following ionization of the corresponding electron orbital. The energy of the absorption edge varies in a systematic way from one element to another. The form of the graph in Figure 4 also shows that X-ray photons of energy just above the absorption edge are the most efficient at promoting excitation that results in X-ray fluorescence but that this efficiency falls off with increase in photon

**Figure 4** Variation of mass attenuation coefficient of iron and nickel as a function of photon energy (2–40 keV) showing discontinuities associated with the corresponding K absorption edges. The energies of the corresponding K–L<sub>2,3</sub> (K $\alpha$ ) and K–M<sub>2,3</sub> (K $\beta$ ) fluorescence lines are shown.

energy. This observation contrasts with that relevant to electron and proton excitation, where the excitation function continues to increase with increasing particle energy. An underlying trend can also be seen in Figure 4 in that the attenuation of the X-ray beam generally increases the decreasing photon energy.

In assessing the overall fluorescence emission intensity, account must also be taken of the spectral output of the excitation source. As an illustration of this point, the emission characteristics of a typical X-ray tube are plotted in Figure 5. The tube output comprises two components: characteristic fluorescence lines derived from the tube anode and a broad background continuum component. The excitation efficiency is maximized for elements that have absorption edges just below the energy of the characteristic tube lines, where the maximum tube output intensity is observed.

## Scattering Processes

The excitation mechanism that leads to the emission of fluorescence X-rays is called the photoelectric effect. There are, however, two other important mechanisms of interaction between the primary photon beam and sample that have analytical consequences. The first of these interactions, Rayleigh (or elastic)

**Figure 5** Schematic diagram of spectral output (0–60 keV) from a rhodium anode X-ray tube operated at 20, 40, and 60 kV, showing both the characteristic rhodium fluorescence lines and the continuum components of the tube output.

scatter, occurs when the energy of an X-ray photon from the excitation source is absorbed by an atom by interaction with electron orbitals. In Rayleigh scatter, deexcitation results in the emission of an X-ray photon with the same energy as the incident photon but scattered in a randomized direction with respect to the incident photon. The consequence of this phenomenon is that a small fraction of the entire spectrum of the excitation source (**Figure 5**) will be scattered off the sample into the X-ray spectrometer and detected together with the fluorescence X-ray signal. The second important interaction is Compton (or inelastic) scatter. Following excitation of the atom, part of the photon energy is absorbed; the remainder is reirradiated as a ‘Compton scatter’ X-ray photon of reduced energy. The energy ( $E'$ ) (or wavelength,  $\lambda'$ ) of the scattered photon is related to its incident energy ( $E_0$ ) (or wavelength,  $\lambda_0$ ) and the angle ( $\theta$ ) through which scatter occurs by the relationship

$$E' = E_0 / (1 + 0.001957E_0(1 - \cos \theta))$$

or

$$\lambda' - \lambda_0 = 0.0243(1 - \cos \theta)$$

Noting that in an XRF spectrometer the angle  $\theta$  is fixed by the design of the instrument, one analytical consequence of this phenomenon is that a fraction of the entire spectrum of the excitation source will be scattered into the X-ray spectrometer with its energy reduced by a constant proportion (or wavelength increased by a constant value). The most obvious

**Figure 6** Spectral scan recorded from quartz showing the Compton and Rayleigh lines observed by scatter of characteristic rhodium anode X-ray tube lines off the sample. The scan is plotted against decreasing spectrometer  $2\theta$  angle, a parameter that is inversely proportional to increasing X-ray photon energy.

manifestation of these two phenomena can be seen when the X-ray spectrum from a sample, excited by the characteristic X-ray lines from an X-ray tube source, is scanned through the region of these lines. The example in **Figure 6** shows the spectrum observed from a sample excited with characteristic  $K-L_{2,3}$  ( $K\alpha$ ) and  $K-M_{2,3}$  ( $K\beta$ ) radiation from a rhodium anode X-ray tube. The rhodium  $K-L_{2,3}$  ( $K\alpha$ ) and  $K-M_{2,3}$  ( $K\beta$ ) lines are observed in the fluorescence spectrum, caused by Rayleigh scatter of tube radiation. The rhodium  $K-L_{2,3}$  ( $K\alpha$ ) and  $K-M_{2,3}$  ( $K\beta$ ) Compton scatter lines are also observed, shifted to a lower energy compared with the main lines. In addition to the very obvious scatter of the characteristic X-ray tube lines, the background present in the spectrum originates mainly from Compton and Rayleigh scatter of continuum radiation from the X-ray tube.

Two important analytical consequences arise from these scatter phenomena. The first is that scatter results in a background contribution to fluorescence spectra, the magnitude of which dictates ultimately the detection limit of the technique. The second is that the intensity of the Compton scatter peak derived from characteristic tube lines from the X-ray source can, in the appropriate circumstances, be used as a simple and effective means of correcting for matrix effects (see next section).

## Matrix Effects – Interactions in the Sample

In the context of XRF, matrix effects refer specifically to attenuation and enhancement phenomena that influence the intensity of fluorescence X-ray lines observed from the sample. As the magnitude of such

matrix effects varies with elemental composition, the observed fluorescence X-ray intensity is not normally linearly proportional to the concentration of the analyte. A correction must, therefore, be applied to measured intensity data to account for the following:

- (1) Attenuation of the primary X-ray beam from the excitation source as it penetrates into the sample. The intensity and spectral distribution of the X-ray flux available to excite the sample changes with penetration depth.
- (2) Attenuation of fluorescence X-rays as they escape through the sample prior to detection by the X-ray spectrometer.
- (3) Secondary fluorescence or second element effects. In circumstances where the energy of a fluorescence photon (e.g., nickel K–L<sub>2,3</sub> at 7.47 keV) lies immediately above the absorption edge of a second element (e.g., iron K-line edge at 7.11 keV) (Figure 4), the fluorescence intensity of the second element (iron K–L<sub>2,3</sub>) will be enhanced due to preferential excitation by fluorescence radiation (i.e., nickel K–L<sub>2,3</sub>) within the sample. The magnitude of this effect is not always significant except for certain combinations of elements in alloys (e.g., iron–chromium–nickel) and in multilayer thin films.
- (4) Tertiary fluorescence or third-element effects are occasionally significant when secondary fluorescence effects are extended to a third element.

## Critical Penetration Effects

One consequence of the attenuation of fluorescence of X-rays within a sample is that a critical depth below the surface of a sample can be identified, beyond which any emitted photon is essentially totally

absorbed and so will not make a significant contribution to the detected fluorescence spectrum. This critical penetration depth varies as a function of matrix composition as well as of fluorescence photon energy. Values for selected elements in an oxide material (a silicate rock, prepared as a compressed powder pellet) and a metallurgical sample (a steel) are listed in Table 3. These data show that the critical penetration depth of low-energy photons (e.g., the K–L<sub>2,3</sub> (K $\alpha$ ) lines of carbon or sodium) is very small, the analytical results being representative of the surface layers of the sample. Conversely, for more penetrating fluorescence radiation, critical penetration depths can exceed several millimeters. In the direct analysis of some matrix types (e.g., lead in petrol, barium in oil), it is important to ensure that the sample presented for analysis is sufficiently thick to exceed the appropriate critical value; otherwise, the analytical signal will vary as a function of sample thickness as well as of analyte concentration.

## Thin Film Criteria

A complementary way of considering these attenuation phenomena is to identify the limiting thickness of a sample below which absorption/enhancement effects are essentially negligible and so relevant matrix corrections may be ignored. Analysis of such thin films may then be undertaken without applying any matrix corrections. By convention, a 1% attenuation is normally taken as the limit for thin film criteria, and some representative values are also listed in Table 3. Satisfying thin film criteria is particularly important in applications such as direct analysis of dust particles collected on a filter membrane, which then serves directly as the sample substrate for XRF spectrometry.

**Table 3** Critical penetration depth and thin film criteria for selected lines in silicate and steel matrices

Element	X-ray fluorescence K–L <sub>2,3</sub> (K $\alpha$ ) line		X-ray tube	Critical penetration depth ( $\mu\text{m}$ )		Limiting thin film thickness ( $\mu\text{m}$ )	
	keV	$\lambda$ (Å)		Silicate	Steel	Silicate	Steel

Data for silicates (analyzed as a compressed powder pellet) taken from Potts PJ (ed.) (1987) *A Handbook of Silicate Rock Analysis*. Chs. 8 and 9. Glasgow: Blackie. Data for steel (analyzed as a solid billet) calculated using a similar procedure. 1 Å = 0.1 nm.

## Matrix Correction Procedures

Since the majority of materials analyzed using XRF are prepared as solid samples (of infinite thickness), matrix correction procedures must be applied to fluorescence measurements. Several approaches are described in this section, their use depending on both the application and the range of elements to be determined.

### Fundamental Parameter Approach

An exact mathematical expression, based on the so-called Sherman equations, may be used to calculate the intensity of fluorescence radiation from a given analyte in a specified matrix using a specified excitation source. This expression is based on a physical model of the excitation process and requires accurate values for the various relevant physical parameters. As originally conceived, the spectral distribution (intensity versus energy) of the excitation source must also be known accurately. This mathematical model accounts for both the attenuation of X-ray photons from the excitation source that penetrate into the sample and the attenuation of fluorescence X-ray photons as they traverse out of the sample prior to detection. A subsidiary correction accounts for second-element enhancement effects. All these terms are dependent not only on photon energy but also on the sample composition, which is not known prior to an analysis. Accordingly, the correction must be applied in an iterative manner. Uncorrected concentrations are first used to estimate the matrix correction factors and so apply a first approximation of the matrix effect. Having applied this correction to analytical data, partially corrected concentration values are used to improve the accuracy of the correction during the next cycle of calculations. The correction is programmed to stop after typically five or six iterations, when differences in corrected values between two successive cycles are statistically insignificant. Early application of this model was restricted by the lack of adequate computational power, some uncertainty in the accuracy of fundamental parameters, and limitations in accurate modeling of the spectral distribution emitted by an X-ray tube. However, these difficulties have largely now been overcome. One advantage of the fundamental parameter approach is the option to quantify results without the necessity for making measurements on calibration samples. However, although valuable, in the semiquantitative analysis of unknown sample types, most quantitative applications would use an adaptation of fundamental parameter procedures (described below) in which a number of standard samples are used to calibrate for the major element components of the matrix.

### Empirical Correction Models

Empirical matrix correction procedures do not attempt to model the physical processes of excitation and attenuation of fluorescence X-rays. Rather, the assumption is made that the intensity of fluorescence emission is influenced by the presence of all elements present in the sample and that the magnitude of this effect can be described by the appropriate parameters called influence coefficients. A family of empirical correction models has been developed over the years, each differing slightly in precise formulation and application. However, these correction models may be divided generally into two categories, those based on fluorescence intensities and those based on concentration.

One of the earliest intensity-based models to gain widespread acceptance was that of Lucas-Tooth and Price (which was subsequently amended by Lucas-Tooth and Pyne to reduce the influence of instrumental drift) and has the form

$$C_i = (a_0 + a_i I_i) - (1 + \sum_{ij} \alpha_{ij} I_j)$$

where  $C_i$  is the weight fraction of element  $i$  of measured intensity  $I_i$ ,  $a_0$  and  $a_i$  are the linear calibration constants (the term  $a_0 + a_i I_i$  is, therefore, the apparent concentration),  $\alpha_{ij}$  is the parameter that describes the influence of element  $j$ , of measured intensity  $I_j$ , on element  $i$ , and the summation is performed over all elements,  $j \neq i$ .

This form of correction procedure is still widely used and offers the advantage that it is based on the intensity of matrix elements, a knowledge of concentration data not being required. Its application is usually best restricted to samples that vary over a limited concentration range. An alternative approach, based on a concentration model, is that of Lachance and Traill, who related the concentration (weight fraction) of element  $i$  ( $C_i$ ), to the concentrations of all other elements present ( $C_j$ ,  $C_k$ , ...) through the empirical expression

$$C_i = (a_0 + a_i I_i)(1 + \sum_j \alpha_{ij} C_j)$$

where  $\alpha_{ij}$  is the influence (or  $\alpha$ ) coefficient that describes the effect of element  $j$ , of concentration  $C_j$ , on element  $i$  ( $\alpha_{ij}$  is assumed to be a constant for samples of a particular matrix type prepared in the same form for analysis). This correction must be applied in an iterative manner, and concentration data for all matrix elements must be known.

Correction procedures of this type offer the considerable advantage that they are not limited by uncertainties in the magnitude of fundamental parameters, nor is there any requirement to model

the X-ray source intensity characteristics. However,  $\alpha$  coefficients may only be calculated successfully from measurements made from a large number of samples of accurately known composition that cover an adequate concentration range. If  $n$  elements are to be determined, a minimum of  $2n$  calibration samples is considered desirable to avoid 'trivial' solutions to the resultant set of simultaneous equations. Although the procedures of Lucas-Tooth and Pyne and of Lachance–Traill are two of the better known empirical correction models, other forms of equation have been proposed including those of Rasberry–Heinrich, Claisse–Quentin, and de Jongh.

### Hybrid Correction Models

To offer maximum analytical flexibility, correction models available on modem systems often combine the best characteristics of both fundamental parameter and empirical correction models. The basis for such 'hybrid' correction models (sometimes known as fundamental coefficient or theoretical  $\alpha$  correction models) is that the empirical  $\alpha$  coefficients used in concentration correction models such as those of Lachance–Traill or Claisse–Quentin can, in fact, be calculated from fundamental parameters. A typical approach, therefore, would be to make measurements on well-characterized calibration samples to determine the  $\alpha$  coefficients of the more important major elements (i.e., elements present in the wt% range, which will have the greatest influence on the overall matrix effect). The  $\alpha$  coefficients for minor and trace elements may then be calculated conveniently from fundamental parameters. In this way, accurate and practical matrix corrections may be derived from fewer calibration standards. In theory, it is not necessary to make analytical measurements on all major elements, although to achieve results of the highest accuracy, it would be unusual if this were not undertaken.

### Compton Scatter

The Compton scatter matrix correction is based on the observation, referred to above, that the intensity of the Compton scatter peak is inversely proportional to the bulk matrix attenuation correction factor. Matrix corrections may then be applied by simply normalizing all fluorescence measurements from a sample to the intensity of the Compton scatter line derived from one of the characteristic fluorescence lines from the X-ray source. This procedure is, however, subject to an important restriction. Corrections are only valid providing no significant absorption edge intervenes between the energy of the Compton scatter peak and the fluorescence line

energy. An extension to lower-energy fluorescence lines can be achieved, providing the matrix characteristics of this and any additional absorption edges are applied as part of the correction, possibly using a supplementary fundamental parameter calculation. In practice, the Compton scatter correction is used widely in the determination of the heavier trace elements, particularly in light matrices. Under these circumstances, it is not necessary to analyze any matrix elements, a factor that may be an additional advantage of this correction procedure in some applications.

## Sample Preparation Requirements

### Forms of Sample Presentation

To exploit the quantitative capabilities of XRF spectrometry, samples must normally be placed in a sample cup designed so that the lower surface is flat and can be mounted accurately and reproducibly in the analysis position, the distance between sample and excitation source being particularly important. The appropriate method of sample preparation depends on the application and the form and nature of the sample. Provided small variations in packing density do not influence the reproducibility of results in relation to fitness-for-purpose requirements, granules and powdered materials, as well as oils, bones, and liquors of high salt content, may be analyzed directly after pouring into a suitable sample cup. The lower surface of this cup must be formed from a thin membrane (e.g., 6  $\mu\text{m}$  Mylar) that does not attenuate fluorescence X-rays of interest to an excessive extent. However, it should be noted that samples cannot be analyzed with the spectrometer in its normal state (i.e., under vacuum) – as referred to above, a helium back-flush facility must be used instead. Dust from air samples collected on membrane filters may be mounted in a suitable holder and excited directly. Metallurgical samples can be cast in the form of a cylindrical billet, one surface of which is then ground flat for analysis.

However, for many sample types, including ceramics, refractories, rocks, ores, soils, etc., results of the highest precision can only be obtained after crushing and grinding (to obtain a representative sample) and preparing samples for analysis in a reproducible form as either compressed powder pellets or glass disks.

### Compressed Powder Pellets

Compressed powder pellets represent a simple, rapid, and cheap sample preparation scheme, which is appropriate for a variety of applications involving

analysis of powdered materials. The sample powder (7–10 g) is mixed with a binder, placed in a suitable die, and compressed to form a flat cylindrical disk, which after drying may be analyzed directly. A range of binders and/or backing materials may be used, but one of the more successful ones is a solution of polyvinylpyrrolidone–methyl cellulose. Several drops are mixed with the sample powder to form a ‘dry’ slurry. After compressing, the powder pellet is dried in an oven to remove the solvent, leaving a minimal mass of binder in the sample to be analyzed. This form of sample preparation is appropriate for a range of applications, particularly in the determination of heavier trace elements in oxide or silicate matrices. However, owing to limitations caused by particle size effects in relation to critical penetration depth, powder pellets are not normally suitable for determination of elements from lower-energy fluorescence lines, in particular elements lower in atomic number than potassium or calcium in the periodic table.

### Glass Disks

The sample preparation scheme described above is not satisfactory if (1) differences in the size, shape, or composition of individual particles present in the powdered material cause variations in the attenuation of low-energy fluorescence X-rays (as in the determination of sodium, magnesium, aluminum, and silicon in geological samples) or (b) ‘absolute’ calibration procedures, that is, calibrations based directly on the measurement of high-purity chemical reagents, must be used to satisfy a standard scheme of analysis in the characterization of ores, refractories, and industrial minerals. Under these circumstances the mineralogical structure of the sample must be broken down by fusing 0.1–0.5 g of sample with a suitable flux and pouring the melt into a preheated mould and cooling (or alternatively squashing flat after pouring onto a suitable platten) to form a flat glass disk. The choice of flux depends on the nature of the sample to be analyzed. Many fluxes are based on lithium metaborate and/or lithium tetraborate since this flux has the capability of dissolving a range of oxide and aluminosilicate materials when fused at 1000–1100°C in nonwetting platinum (5%)–gold crucibles. A selection of fluxes and dilution factors appropriate to a range of different materials are listed in Table 4. The particular advantages of this form of sample preparation are that the surface layers of the glass disk are representative of the bulk material, so facilitating accurate determination of elements such as sodium from fluorescence X-rays with short critical penetration depths (see Table 3). Furthermore, it is simple to prepare

**Table 4** Fluxes available for the preparation of glass fusion disks from various sample types

Sample type	Flux composition	Flux: sample ratio (by wt)
Aluminosilicates, calcium silicates (e.g., cement, anorthosite), bone china, phosphate rock, apatite, calcium sulfate, fluorspar, zircon, glasses, glazes, frits	4 LiBO <sub>2</sub> : 1 Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub>	5:1
Chrome ores, chrome magnesite refractories (10–50% Cr <sub>2</sub> O <sub>3</sub> )	5 Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> : 4 LiBO <sub>2</sub>	22.5:1
Dolomite, limestone	Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub>	5:1
Magnesia, magnesite	Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub>	10:1
Titania (rutile, ilmenite, stabilized zirconium), iron oxides, manganese oxide	Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub>	12:1
Silicon carbide, silicon nitride, silicon boride, elemental silica	Li <sub>2</sub> B <sub>4</sub> O <sub>7</sub> :Li <sub>2</sub> CO <sub>3</sub>	5:1 to 12:1 (various ratios)

Abstracted from Bennett H and Oliver GJ (1992) *XRF Analysis of Ceramics, Minerals and Allied Materials*. Chichester: Wiley.  
LiBO<sub>2</sub>, lithium metaborate; Li<sub>2</sub>B<sub>4</sub>O<sub>7</sub>, lithium tetraborate; Li<sub>2</sub>CO<sub>3</sub>, lithium carbonate.

‘standard’ disks for calibration by fusing appropriate proportions of chemical reagents to match the composition range of samples to be analyzed. An additional advantage is that fusion techniques are effective in producing a homogeneous glass disk from samples containing refractory mineral grains (e.g., zircon) that are difficult to dissolve using acid-based dissolution procedures used in some competitive atomic spectrometry techniques.

### Introduction

The analytical capabilities of X-ray fluorescence (XRF) have been recognized since the work of Moseley, who, in 1913 and 1914, published papers describing the systematic variation in fluorescence wavelength with atomic number and used this observation to characterize the elemental composition of brass. However, the performance of early instrumentation was restricted by various technical difficulties, and it was not until 1948 that the prototype of the first commercial wavelength dispersive (WD)-XRF instrument was described by Friedman and Birks. Commercial instrumentation became available during the mid-1950s and was progressively adopted by laboratories involved in elemental analysis of the range of sample types described in the preceding article. WD-XRF instrumentation offered significant advantages in terms of sensitivity, precision, and speed of analysis in the determination of a wide range of elements compared with competitive techniques (then wet-chemical methods and arc/spark source optical emission spectrometry). Despite the more recent introduction of alternative instrumental techniques of high analytical sensitivity and productivity, WD-XRF spectrometry has withstood the test of time and remains the technique of choice in many applications where its distinctive analytical characteristics can be exploited.

### Categories of Instrumentation

Two principal categories of WD-XRF instrument have been developed. Sequential instruments, shown schematically in **Figure 1**, are designed with one (or more) WD spectrometers. Multielement analysis of samples is undertaken by driving the spectrometer to a preselected set of peak and background angles in a programmed sequence and recording the X-ray count rate at each rest position for a specified count time. Depending on application, a single analysis for 15–20 elements, involving 30–40 separate spectrometer movements may take typically 20 min. If analytical requirements change, the analyst can re-program the instrument to determine an alternative set of elements, so offering maximum analytical flexibility in laboratories involved in research and development applications.

A second category of instrument is the simultaneous WD-XRF analyzer. This instrument is designed with a specified number (usually in the range 8–20) of individual fixed spectrometer ‘channels’, each optimized for the determination of a designated element. Multielement analysis is undertaken very rapidly by acquiring data simultaneously from all channels. Such instruments offer, therefore, high analytical productivity of benefit in production and quality control laboratories that are required to analyze the same sample-type on a routine basis.

Additional flexibility can be obtained by installing a movable goniometer channel (normally substituted for one or two fixed channels), which can be programmed to determine additional elements or scanned to provide qualitative analysis data. The analytical specification of this goniometer is not usually as high as those fitted to sequential instruments.

Elemental determinations by WD-XRF are undertaken by measuring the background-corrected fluorescence intensity of a series of X-ray lines and comparing these data with the appropriate calibration and matrix correction functions. To undertake these measurements, instrumentation comprises: (1) an X-ray tube and accompanying high-voltage generator; (2) a sample holder and mechanism to exchange the sample; (3) a WD X-ray goniometer assembly, including entrance slits, diffracting crystal,

**Figure 1** Schematic diagram of a WD-XRF analyzer showing X-ray tube, sample, and sample holder and components of the X-ray spectrometer.

and X-ray proportional counters; (4) signal-processing and acquisition electronics; and (5) computerized control for instrument operation and data processing. The principal analytical characteristics of these components will now be considered.

## X-Ray Tube

The X-ray tube (Figure 2) is the source of high-energy X-ray photons used to excite characteristic fluorescence radiation in the sample. The X-ray flux is generated when a beam of electrons, emitted from an incandescent filament, is accelerated through a large potential difference (normally in the range 20–100 kV) and directed at a metallic anode. Interactions between the electron and anode result in ionization of inner orbital electrons from atoms of the anode, resulting in the emission characteristic fluorescence X-rays. This phenomenon is very similar to the X-ray fluorescent excitation mechanism, except that atoms are excited directly by energetic electrons, rather than by X-ray photons. Interaction of the electron beam with atoms of the anode results in the emission of a second category of X-ray radiation, a bremsstrahlung or continuous X-ray emission. This emission results from the deceleration effect that occurs when electrons are slowed by the electric fields associated with atoms of the anode. The spectrum of this continuous radiation extends up to an energy equivalent to the accelerating potential applied to the tube. Spectral output from the X-ray tube consists, therefore, of intense fluorescence lines characteristic of the tube anode material, accompanied by a broad continuum radiation.

Choice of tube anode influences the analytical capabilities of the instrument, since a specific range of elements that have absorption edges just below the energy of the characteristic tube lines will be excited with maximum sensitivity. In several applications (including geological), the rhodium (Rh) anode tube is considered to be a 'universal' tube because the Rh

K lines efficiently excite a range of heavier trace elements, whereas the Rh L lines are available to boost the excitation of the lightest elements. However, in other applications, molybdenum, chromium, silver, gold, tungsten, scandium, cobalt, and gadolinium anode tubes all offer specific benefits.

To maximize sensitivity, up to 4 kW of power is dissipated by a typical WD-XRF tube. Efficient water cooling is, therefore, essential to prevent damage and premature aging of the tube. Two categories of tube design are available, using either a side- or an end-window configuration. In the side-window design, the filament is held at high negative potential to achieve the required potential difference relative to the anode, at ground potential. This design offers the advantage of being capable of supporting potential differences of up to 100 kV. However, electrons that are backscattered from the anode, impinge onto the beryllium exit window, fitted to maintain high vacuum within the tube. These backscattered electrons heat the window, which must, therefore, be made of a reasonably thick beryllium foil to provide adequate mechanical strength. As a consequence, excitation of the lowest atomic number elements may be reduced because of absorption of the low-energy photon flux within the beryllium window.

In contrast, end-window X-ray tubes (Figure 2) are designed to operate with a reverse bias (i.e., a positive potential) applied to the anode. With this arrangement, the flux of backscattered electrons impinging on the entrance window is reduced significantly, since they are attracted back into the anode, which is held at a high positive potential. Two analytical advantages result. First, the beryllium exit window may be made of thinner foil, reducing the attenuation of low-energy X-ray output with a beneficial effect on the excitation of low atomic number elements. Second, it is easier to design the tube so that it can be positioned closer to the sample, increasing the excitation coupling efficiency. End-window tubes are normally designed to operate at a maximum potential of 60–75 kV (rather than the 100 kV of the side-window design), and are significantly more expensive to construct. A more sophisticated cooling supply is required to prevent breakdown of the high voltage applied to the anode.

The X-ray tube is powered by an appropriate generator capable of being programmed by the operator to apply a potential of typically between 20 and 60–100 kV (depending on tube design) at up to 4 kW. The success of typically modern WD-XRF instrumentation depends in part on the very high degree of stability with which the X-ray output intensity of the tube can be maintained.

**Figure 2** Schematic diagram of an end-window X-ray tube.

## Sample Holder

To achieve high analytical precision, samples must be mounted in the instrument in a highly reproducible manner to avoid discrepancies in excitation efficiency. Because of the small distance between the X-ray tube and the sample, even very small discrepancies in the repositioning height of the sample can have a significant effect on measured fluorescence intensities. Sample cups, 30–50 mm in diameter, are used to hold the analyzed surface in a precise reference plane relative to the X-ray optical path of the instrument (Figure 1). The design of these sample holders varies depending on whether the requirement is to analyze solid disks, loose powders, or liquids, for example. For the latter two categories, the sample must be supported on a thin membrane (e.g., 6  $\mu\text{m}$  Mylar), which minimizes the attenuation of low-energy fluorescence radiation. Samples are normally transferred from an external automatic sample changer into an intermediate chamber, which is evacuated before the sample is finally transferred to the analysis position. During analysis, samples are normally rotated at a few revolutions per second to minimize any variations caused by unevenness in the analyzed surface or inhomogeneity effects. Although the spectrometer chamber would usually be operated under vacuum to avoid attenuation of the lower-energy fluorescence spectrum by the atmosphere, such conditions are incompatible with the analysis of liquids or loose powders, which require the spectrometer to be flushed with helium gas at atmospheric pressure.

## Wavelength Dispersive X-Ray Spectrometer

The WD spectrometer (Figure 1) behaves as an X-ray monochromator. Selected crystalline materials are used to diffract lines in the fluorescence X-ray spectrum. When a beam of X-rays is directed at certain crystalline materials, X-ray photons are reflected off the various atomic layers in the crystal. Destructive interference occurs between almost all reflected photons, except those that satisfy the Bragg equation:

$$n\lambda = 2d \sin \theta$$

where  $n$  is an integer (1 for first-order diffraction, 2 for second-order diffraction, etc.),  $\lambda$  is the wavelength (nm) of the X-ray photon,  $d$  the crystal lattice spacing (nm) of the diffracting medium, and  $\theta$  the angle of incidence subtended at the crystal.

The Bragg crystal spectrometer consists of (1) an entrance slit or collimator, (2) the diffracting element, (3) an X-ray proportional counter, and (4) a

goniometer mechanism to maintain the correct geometric relationship between these components (Figure 1). Most WD-XRF spectrometers are of a semifocusing design and are fitted with parallel-blade collimators and flat diffracting crystals. In the more specialized fully focusing design, a curved crystal is used to diffract the X-ray beam to a line focus at slits placed in front of the proportional counter. Provided certain geometric constraints are satisfied, this second design is more efficient at diffracting fluorescence photons and is often used in fixed channel spectrometers, and electron microprobe instrumentation. These principal components of the X-ray spectrometer are described below.

### Entrance Collimator

As fitted to conventional flat crystal spectrometers, the entrance collimator, comprising a series of parallel blades known as Soller slits, is required to restrict the angular divergence of fluorescence X-rays accepted for diffraction, so avoiding a significant loss in spectrometer resolution. A choice of blade spacings is normally available on modern spectrometers to match the angular dispersion requirements of the diffracting crystal selected for use.

### Diffracting Element

A number of diffracting elements is required to measure the range of fluorescence lines used in most analytical applications (see Table 1 for details). These diffracting elements are selected on the basis of several properties, including: (1) appropriate  $2d$  lattice spacing, given the angular movement that can be achieved on the spectrometer; (2) high reflectivity (i.e., high intensity in the diffracted beam); (3) satisfactory dispersion power and resolution (to give adequate separation between lines in the diffracted spectrum); (4) ability to suppress multiple-order diffractions; (5) physical properties, including low coefficient of thermal expansion (to minimize shifts in the position of diffracted peaks with changes in temperature), stability in air and under vacuum, resistance to moisture, and ability to be attached to a curved substrate (if appropriate) without cracking.

The majority of diffracting elements are crystalline materials (Table 1). However, two other categories of materials have found widespread use in the low-energy (long-wavelength) fluorescence X-ray region (particularly for the elements between boron and magnesium in the periodic table). These are:

(1) *Langmuir–Blodgett ‘pseudocrystals’*. These are usually fabricated from the lead soap compounds (e.g., lead stearate) and are made by coating alternate layers of lead stearate molecules onto a suitable

**Table 1** Details of diffracting crystals commonly used in WD-XRF

Crystal specification		2d spacing (nm)	Typical K-line range	Application and comment
Lithium fluoride	LiF(200)	0.285	K–U	Standard 'heavy-element' crystal
Lithium fluoride	LiF(220)	0.403	V–U	Offers improved resolution but lower intensities than LiF(200)
Lithium fluoride	LiF(420)	0.180	Ni–U	Offers improved resolution but lower intensities than LiF(200) and LiF(220)
Germanium	Ge(111)	0.653	P–Cl	Crystal suppresses second-order interference effects (e.g., from second-order Ca K–L <sub>2,3</sub> on P K–L <sub>2,3</sub> )
Pentaerythritol	PET (002)	0.874	Al–Cl	General-purpose crystal for this range of elements
Indium antimonide	InSb(111)	0.748	Si	Higher intensities in determination of Si than competitive crystals
Thallium hydrogenphthalate	TAP	2.58	O–Mg	General purpose crystal for this range of elements
Layered synthetic microstructure (e.g., W/Si)		5–6	O–Mg	Higher intensities but lower resolution than TAP
Layered synthetic microstructure (e.g., V/C)		11–12	C	Specialized application in the determination of C
Layered synthetic microstructure (e.g., MoB <sub>4</sub> /C)		20–24	B	Specialized application in the determination of B

substrate. In this way, diffracting elements with lattice spacings of typically between 8 and 14 nm can be fabricated. These pseudocrystals are rarely used on modern WD-XRF spectrometers, their role being largely superseded by multilayer dispersion elements.

(2) *Multilayer dispersion elements* (or layered synthetic microstructures). These are artificially manufactured diffraction devices made by depositing alternate layers of a low atomic number element (e.g., silicon, carbon) and a high atomic number element (e.g., tungsten, vanadium, molybdenum, nickel) onto a suitable substrate. The high atomic number layers are designed to reflect the X-ray beam and are separated by the relatively transparent low atomic number layers. By careful control of the deposition process, diffracting elements can be fabricated that have almost any selected 2d spacing, typically in the range 4–22 nm. At the present state of development, these devices show higher reflectivity than alternative diffracting crystals, but with some loss of spectral resolution. Multilayers are normally only capable of diffracting satisfactorily the K lines of one or two adjacent low atomic number elements and so several are required, having optimized 2d values, to cover the full range of low atomic number elements of interest. There is currently considerable interest in the further development of the technology for fabricating these devices.

The more common diffracting elements available and used on modern spectrometers are listed in **Table 1**. Selection for installation on a particular instrument would normally depend on the application (based on

the range of elements to be determined), subject to a maximum of between four and nine diffracting devices that can usually be mounted on the crystal exchange mechanism of a single goniometer.

### X-Ray Proportional Counters

The function of the X-ray counter is to measure the intensity of the diffracted X-ray beam and to provide output pulses that are proportional in height to the energy of the detected photon. This provides a means of discriminating against multiple-order interferences by pulse height analysis. Multiple-order interferences are fluorescence X-rays with 1/2, 1/3, 1/4 of the wavelength of interest in compliance with  $n = 2, 3, 4$  in the Bragg equation. Two types of counter are normally used on WD-XRF spectrometers, gas proportional counters and sodium iodide scintillation detectors.

### Gas Proportional Counters

The argon gas flow proportional counter consists of a cylindrical chamber down the center of which passes a small-diameter wire (the anode), to which a positive potential of between 1 and 2 kV is applied (**Figure 3**). The counter gas, argon, is ionized by incident X-ray photons. Under the influence of fields generated by the applied potential, electrons formed by this ionization process drift toward the wire anode. In the immediate vicinity of the anode, electrons are accelerated by the associated high potential fields, causing further ionization by collision with gas molecules. The resultant avalanche of electrons caused

by this 'gas multiplication' effect is discharged at the anode and measured by the counter electronics as an individual X-ray photon signal. Argon ions, also formed by the ionization process, drift to earth at the walls of the counter chamber. To suppress interferences that would be caused by the formation of secondary electrons, generated by the impact of these ions with the wall of the counter, the gas (argon) must contain a small proportion (5–10%) of carbon dioxide or methane as a quench gas. Although related in design to the Geiger–Müller tube, the proportional counter is operated with a lower bias so that

the detected signal is proportional to the number of electrons generated during the primary ionization event (and therefore to the energy of the detected photon). To minimize attenuation of low-energy fluorescence X-rays, a thin membrane (commonly a 1  $\mu\text{m}$  film of polypropylene) is used as the counter entrance window. This window must be strong enough to withstand the spectrometer vacuum against the pressure of the counter gas. However, to compensate for the small rate of diffusion of gas through this window, a continuous flow of argon must be supplied to the counter. Argon flow proportional counters are normally used to detect fluorescence X-rays in the range up to  $\sim 6$  keV. For the higher-energy range, krypton or xenon can be used as counter gas in view of their greater stopping power. In these cases, a thicker window (e.g., 6  $\mu\text{m}$  beryllium foil) can be used, which, being nonporous, allows the counter to be sealed during manufacture ('sealed gas proportional counter'). The applications of these counters are summarized in Table 2.

In simultaneous XRF instruments, individual channels are normally fitted with a gas proportional counter appropriate to the energy of the fluorescence X-ray line to be measured. However, on sequential instruments the argon gas proportional counter is normally paired with a versatile scintillation counter.

### Scintillation Counter

The scintillation counter (Figure 4) is based on a sodium iodide crystal doped with thallium atoms to give it appropriate semiconductor properties ('thallium-drifted sodium iodide scintillation counter'). X-ray photons interact with this crystal, causing it to scintillate, emitting light photons in a band centered at 410 nm in the blue region of the visible spectrum. The detector crystal is optically coupled to the photodiode of a photomultiplier tube. By this means, detected photons are converted into an electronic signal, taking advantage of the large internal amplification factor inherent in the operation of the

**Figure 3** Schematic diagram of an argon gas flow proportional counter.

**Table 2** Proportional counters used in WD-XRF spectrometers

Photon energy range (keV)	Application (K lines)	Proportional counter details
0.2–0.9	B–F	Argon gas flow counter with ultrathin window supported on a grid (e.g., 0.2 $\mu\text{m}$ collodion)
1–10.5	F–As	Argon gas flow proportional counter with standard window (e.g., 1 $\mu\text{m}$ polypropylene)
3.3–8.0	K–Cu	Krypton sealed counter with 6 $\mu\text{m}$ beryllium window
8.6–18	Zn–Mo	Xenon sealed counter with beryllium window
6–30	Mn–Ba	NaI(Tl) scintillation counter

A combination of the standard argon gas flow proportional counter and the scintillation counter is often used on general-purpose XRF instruments, using tandem operation to compensate for the reduced detection efficiency of each, individually, in the 6–10 keV region.

**Figure 4** Schematic diagram of a scintillation counter.

photomultiplier tube. As with gas counters, the detector is operated so that the magnitude of the photomultiplier signal is proportional to the energy of the detected photon. Scintillation counters are not suitable for the detection of X-ray photons below  $\sim 6$  keV (equivalent to manganese  $K-L_{2,3}$  ( $K\alpha$ )). Conversely, whereas argon gas flow counters show optimum efficiency for lower-energy X-ray photons, they become less efficient in the detection of X-ray photons above the 6–10 keV region (i.e., manganese to arsenic  $K-L_{2,3}$  ( $K\alpha$ )). To optimize detection of fluorescence radiation in this intermediate X-ray region, instruments are normally provided with either (1) an additional krypton sealed proportional counter, which must be mounted on the goniometer independently of the other counters; or (2) a tandem arrangement (Figure 1) of the argon gas flow proportional counter (provided with entrance and exit windows) and scintillation counter. In the intermediate region between  $\sim 6$  and 10 keV, the signal from the gas proportional counter is summed with that from the scintillation counter, the latter deriving its signal from photons that pass straight through the flow counter without interaction.

### Goniometer Mechanism

To satisfy the Bragg equation, a precise angular relationship must be maintained to ensure that for any angle of incidence  $\theta$  at the diffracting crystal, the proportional counter views the diffracted beam through a total angle of diffraction of  $2\theta$ . The simplest way of maintaining this angular relationship is to mount the diffracting element and proportional counters on separate ' $\theta$ ' arms, linked by 2:1 gearing to control their relative movements. However, alternative arrangements have been developed, notably goniometers in which the movement of the diffracting element and proportional counters (each of which may be mounted on individual arms) can be controlled independently. In both cases, great care is taken to ensure that high precision is achieved in the angular

resetting of the goniometer with minimum backlash, and without compromising the speed with which the mechanism can be slewed from one angle to the next.

### Pulse Height Analysis

Interferences arise in wavelength dispersive spectrometers from the diffraction of multiple-order lines (i.e.,  $n = 2, 3$ , etc., in the aforesaid Bragg equation). Although multiple-order diffractions are progressively less intense than those in the first order, some element specific interferences can be troublesome in certain matrices (for example, the fluorine  $K-L_{2,3}$  ( $K\alpha$ ) line suffers a spectrum interference from a third-order diffraction of phosphorus  $K-L_{2,3}$  ( $K\alpha$ )). Furthermore, multiple-order diffraction of higher-energy tube continuum radiation scattered off the sample is likely to contribute to the spectrum background of all analytical measurements. These effects can be minimized by use of pulse height analysis. The signal derived from the X-ray counter (which is proportional to the energy of the detected X-ray photon) is filtered electronically by setting upper and lower discriminator levels, which must normally be optimized by the user. The lower-level discriminator is set to eliminate electronic noise from the counting circuits and the upper-level discriminator set to reject multiple diffraction events that will have a pulse height that is  $\times 2$ ,  $\times 3$ , etc., times the height of the fluorescence X-ray of interest. Only events that pass through this electronic 'window' contribute to the analytical signal. Thus, with the discriminators set to accept pulses corresponding to first-order fluoride  $K-L_{2,3}$  ( $K\alpha$ ) photons, the third-order phosphorus  $K-L_{2,3}$  ( $K\alpha$ ) signal, which will have a pulse height distribution larger by a factor of three, will be effectively suppressed.

### Optimizing Conditions for Analysis

Several factors, often interrelated, are involved in the development of an analytical program. Sample

preparation requirements and choice of X-ray tube in relation to the analytical application have been considered in the preceding entry. More specific features are summarized below.

### Excitation Conditions

A suitable procedure for optimizing the potential applied to the X-ray tube in XRF spectrometry is to analyze a representative sample at a range of kV settings and to choose the setting that maximizes the value of the figure-of-merit ( $\sqrt{I_p} - \sqrt{I_b}$ ) where  $I_p$  is the peak and  $I_b$  the background count rate of a chosen fluorescence line. For multielement determinations, compromise conditions must be selected. It is common practice to select an operating potential of  $\sim 30$ – $40$  kV for the determination of K lines in the region sodium–iron, and between  $60$  and  $100$  kV (depending on the capacity of the generator and design of the X-ray tube) for the determination of the K lines of higher atomic number elements. Tube current is selected to deliver tube power at the maximum (or near-maximum) rating.

### Spectrometer Parameters

Only in unusual circumstances would the fluorescence line selected for analysis not correspond to the most intense line K– $L_{2,3}$  ( $K\alpha$ ) line (or  $L_3$ – $M_{4,5}$  ( $L\alpha$ ) line for higher atomic number elements) available in the analytical region from  $1$  to  $20$  keV. Exceptions to this rule are the occasional necessity to avoid severe spectral overlap interferences. For example, in some applications it would be appropriate to select the lead (Pb)  $L_2$ – $M_4$  ( $L_1\beta_1$ ) rather than the more intense Pb  $L_3$ – $M_5$  ( $L\alpha_1$ ) line to avoid a severe spectral overlap interference from arsenic K– $L_{2,3}$  ( $K\alpha_{1,2}$ ). Other ‘classic’ overlap interferences where similar considerations may apply include titanium K– $L_{2,3}$  ( $K\alpha$ )/barium  $L_3$ – $M_5$  ( $L\alpha_1$ ), and yttrium K– $L_{2,3}$  ( $K\alpha$ )/rubidium K– $M_{2,3}$  ( $K\beta$ ). Accepting these reservations, choice of diffracting crystal, proportional counter, and spectrometer angle are exemplified by those listed in Table 3. Choice of count time would depend on the analytical application and the expected range of concentrations in the samples to be analyzed. A balance must be achieved between adequate precision (or detection limit) and acceptable analysis time. On modern WD-XRF instruments, it would be unusual to select a count time of longer than  $\sim 100$  s (per line), while less than  $10$  s may be sufficient for the most sensitive major elements. One guideline is to select a count time that will result in the accumulation of say  $100\,000$  counts in a measurement.

### Background Corrections and Spectral Interferences

A background correction, necessary in almost all XRF applications, is normally undertaken on sequential WD-XRF instruments by measuring the count rate at a spectrometer angle offset from the peak angle. If the background slopes in this region of the spectrum, measurements on either side of the peak may be necessary, the appropriate value being calculated by interpolation of these data. Background correction may be relatively trivial in the determination of a major element in a high atomic number material (where background scatter off the sample is relatively small), but is significant in the analysis of low atomic number matrices (e.g., oxides and silicates) and is very important in the determination of any trace elements approaching the detection limit level. Background angles must be free of interference from unsuspected fluorescence emissions; those angles selected for one sample type may not all be appropriate for another (Figure 5). More sophisticated approaches are available in which the variation of background intensity is modeled over a range of sample matrices so that curvature of background and mass attenuation effects may be taken into account.

In general, spectral interferences are well characterized in XRF. Where significant overlap occurs, the ratio method is often used to make the appropriate correction. The intensity ratio is measured at the spectrometer angle of the analyte relative to that at an adjacent fluorescence line of the interfering element using a sample that does not contain the analyte. In the analysis of a sample, the magnitude of the interference correction can then be calculated knowing the value of the appropriate interference ratio factor, from measurements of the adjacent fluorescence line of the interfering element.

### Monitoring for Drift

Modern instrumentation offers very high stability so that it is necessary to recalibrate only after extended periods of operation (in the extreme, after replacement of the X-ray tube or components in the spectrometer). However, provision must be made to compensate for small day-to-day variations in instrument response. By normalizing count data to equivalent measurements from one or more drift monitor samples, which are counted periodically during each analytical run, small variations in the slope and offset of the calibration function may be made. The drift monitor samples are normally chosen to be the same samples that were used to normalize count data during the calibration run and will

need replacing periodically to avoid the effects of long-term damage from exposure to X-rays.

### Calibration Procedures

There are several factors that influence the choice of calibration procedure including: (1) selected sample preparation procedure; (2) selected matrix correction procedure; (3) availability of well-characterized reference samples; and (4) requirement to follow a 'standard' scheme of analysis.

Often, the simplest and most convenient calibration procedure is to analyze a range of reference materials, or samples that have been characterized by independent analytical techniques. This procedure is often the only practical method available if samples are to be analyzed in the consolidated state (e.g., as

compressed powder pellets or metallic disks). In these circumstances, it is important that a sufficient number of reference samples are available to cover the range of concentrations and compositions for which determinations are required.

An alternative strategy is appropriate if determinations are to comply with a standard scheme of analysis, such as those developed by the British Standards Institution for the analysis of ceramic and refractory materials. In these schemes, samples are prepared as fused glass disks and calibration samples may then be prepared in the same way using specified proportions of high-purity element oxides. This calibration procedure can, therefore, be considered to be 'absolute' in contrast to the 'relative' measurements made against reference samples.

Before results from a new calibration are accepted, it is essential that the accuracy over the full calibration range is validated independently. Although the intensity response of a WD spectrometer is expected to be linear over six orders of magnitude (subject to corrections for counter dead-time effects), the accuracy of the calibration function is as sensitive as that for any other instrumental technique to the effects of bias, which are likely to be most significant in the analysis of samples at the extremes (low or high) of the calibration range. Discrepancies of this nature are sometimes caused by the use of inaccurate values in reference samples. These discrepancies can only be overcome satisfactorily by a critical evaluation of all calibration data. If the analysis of independently characterized reference materials cannot be used in this evaluation (because, for example, these samples have had to be used as primary calibration samples) then it is possible, though not entirely satisfactory, to evaluate the self-consistency of calibration data in order to identify discrepant points.

### Routine Analysis

Routine XRF analysis typically involves loading a batch of samples together with drift normalization monitors and appropriate quality assurance samples onto an automatic sample changer. Sample names, loss-on-ignition data (if required by the matrix correction procedure), and sample-to-flux ratio (if appropriate) may be required by the analytical program before the instrument commences to analyze the batch in a specified sequence using precalibrated instrument conditions (e.g., spectrometer parameters including count time and the sequence of peak and background angles to be measured, overlap interference correction factors, calibration function, and matrix correction procedures). In calculating elemental concentrations, individual intensity data must be corrected for background contribution, spectral overlap interference (if appropriate), instrumental drift, and matrix effects (including the influence of unanalyzed low atomic number elements assumed by stoichiometry).

### Performance Parameters

The theoretical precision of XRF count data is described by Poisson statistics such that the ideal standard deviation ( $\sigma$ ) in a measurement involving the accumulation of  $n$  counts can be calculated as  $\sqrt{n}$  and the coefficient of variation as  $(\sqrt{n}/n)$ , which equals  $(1/\sqrt{n})$ . In terms of count rate ( $I$ ),  $n$  is calculated from  $n = I \times t$ , where  $t$  is the count time. In assessing the uncertainty in a net peak measurement,

it is necessary to take into account the contribution resulting from subtracting a background measurement. Over the short term, instrumental contributions to the precision of a series of measurements are likely to be very small, perhaps as low as 0.1% relative so that measured precisions will approach theoretical values predicted by Poisson statistics.

Unlike most other atomic spectroscopic techniques, which normally require repetitive measurements on a blank sample, an estimate of XRF detection limit performance can be made from a knowledge of the appropriate background count rate and elemental sensitivity. Using the theoretical basis outlined above, it can be shown that the lower limit of detection (LLD) (i.e., the  $3\sigma$ , detection limit) can be calculated from:

$$\text{LLD} = 3\sqrt{[2(I_b t)]/(I_p t/C)} = 3\sqrt{(2I_b/t)C/I_p}$$

where  $I_b$  is the background count rate counted for time  $t$ ,  $I_p$  is the peak count rate obtained using the same count time from a sample containing the element at concentration  $C$ , and the factor  $\sqrt{2}$  is required to take into account additional uncertainties in peak and background measurements that are subtracted to calculate the net signal. The factor  $(I_p t/C)$ , incorporated into the above expression, is essentially a sensitivity factor to convert the detection limit signal into a concentration.

Representative detection limit data for a range of elements commonly determined by XRF are listed in **Table 3** and show that the technique is capable of achieving detection limits down to the  $\mu\text{g per g}$  level (referring to the solid sample) from the K lines of elements that are most sensitively excited by the X-ray tube. Detection limits increase for low atomic number elements, in part because of the lower excitation efficiency using photons (electron excitation is more effective for elements below about silicon in the periodic table) and in part because of the attenuation effects of counter windows on low-energy X-ray photons.

### Statistical Process Control

XRF analysis is used widely by laboratories that monitor the routine production of materials. In such applications, analyses are required to confirm that the production process is within specified limits. In these (and other) circumstances, it is important to be able to demonstrate that the instrument response has not drifted beyond acceptable limits for day-to-day operation, otherwise the wrong remedial action might be taken, so affecting the quality of the product. Statistical process control procedures require

that selected quality control samples are analyzed periodically in the course of each analytical run. Results from the quality control samples are then compared with previous data, usually plotted on a control chart, to see if any indications of 'out-of-control-data' are exceeded, such as:

1. The current elemental results lie outside predetermined upper or lower control limits, normally set at  $\pm 3\sigma$  of the expected mean.
2. The present and previous six results all lie above or below the center line of the control chart.
3. Six consecutive points all progressively increase or decrease in value.

If any of these criteria are satisfied, action is required to investigate for analytical drift and recalibrate the instrument, if necessary.

## Qualitative Analysis

WD-XRF is not as effective in the qualitative analysis of unknown samples as energy dispersive (ED)-XRF. However, modern instruments can readily be programmed to scan through selected regions of the spectrum and to identify XRF lines, or to 'line hop' from one target line to the next (Figure 5). If it is necessary to evaluate the presence of minor or trace elements, relatively slow scan rates are necessary to improve sensitivity. Furthermore, if it were necessary to evaluate the presence of all XRF-analyzable elements, separate scans using several crystals would be required. As a powerful aid in identifying unknown samples, rapid semiquantitative analysis can be undertaken by programming the instrument to undertake short count measurements on all relevant elements. Fundamental parameter-type

matrix correction procedures can then be applied to data to quantify results without using calibrants. Such procedures often have the option of taking into account the known (or assumed) concentration of unanalyzable elements (e.g., oxygen, carbon, or hydrogen) from knowledge of the sample type (e.g., specifying the sort of plastic that is being measured). Results from such a procedure will not be as accurate as data from a full matrix-matched calibration program. However, the technique is rapid, does not necessarily require any prior knowledge of matrix composition, and the resultant semiquantitative elemental data may be sufficiently successful in fingerprinting the sample to preclude the necessity for further, more detailed analysis.

## Introduction

Although the principles and mechanism of excitation for energy dispersive X-ray fluorescence (ED-XRF) are exactly the same as for wavelength dispersive (WD)-XRF, the analytical characteristics of ED-XRF instrumentation demonstrate some significant

differences, largely due to the different response characteristics of an ED detector. Traditionally, ED detectors were popularly associated with the Si(Li) detector (lithium-drifted silicon). However, although Si(Li) remains the standard against which other detector types are compared, technological advances have led to the introduction of alternative detector types, not the least the silicon PIN diode, the silicon drift detector, as well as germanium, mercury(II) iodide, and other semiconductor devices. Even the traditional gas proportional counter can

be used as an ED detector in instruments designed for certain dedicated applications. The key feature of all these devices is the 'parallel' mode of data acquisition, that is, the capability of detecting simultaneously the full X-ray spectrum emanating from a sample using a multichannel analyzer to convert detected X-ray events into a spectrum represented as a histogram plotted as channel number (proportional to X-ray energy) versus counts (i.e., X-ray intensity).

This mode of operation offers unparalleled opportunities for qualitative analysis (from a visual appraisal of spectra, or even quantification in real time whilst spectra are accumulating). However, there are also additional criteria in optimizing excitation conditions to maximize the emission of XRF intensities in the region of analytical interest. The reason for this is that whereas the WD X-ray spectrometer is designed as a monochromator, the entire spectrum emitted from an excited sample is available for detection in an ED-XRF instrument.

ED spectrometers have no moving parts and have benefited extensively from the miniaturization that has taken place in integrated circuit technology. To an increasing extent, ED-XRF instruments can be adapted to XRF applications in a much more flexible manner than WD spectrometers. There are a number of reasons for this flexibility, which may be summarized as follows:

1. The parallel mode of ED spectrum acquisition (mentioned above) means that spectra can be displayed and interrogated during acquisition, permitting qualitative identification, and indeed, an estimate of the quantitative composition to be made in a few seconds.
2. A much larger solid angle of the X-ray spectrum emitted by the sample is detected in ED-XRF than by WD spectrometers (where a high degree of collimation is required to maintain an adequate level of spectrum resolution). Using conventional excitation geometries, ED-XRF excitation sources can be up to 100 times lower in intensity than would normally be required for WD-XRF. For this reason, it is relatively simple to use ED systems in polarized excitation geometries (where excitation intensities are substantially reduced during the polarization process) and so take advantage of the consequential improvement in signal-to-background ratios that result from this method of excitation.
3. The spectral resolution of semiconductor ED detectors is inherently worse than that of WD spectrometers for silicon detectors in the spectral region from 0 to  $\sim 20$  keV. Conversely, this type of detector offers a resolution advantage above 20 keV. The

resolution of ED devices is largely controlled by their electronic characteristics, as explained below. The consequence of the poorer resolution in the 0–20 keV region is that in comparison with WD-XRF measurements of equivalent spectra, signal-to-background ratios, detection limits, and spectrum overlap interferences will all be inherently worse, although there are other opportunities available in ED to compensate for these effects (see below).

4. Because of the electronic noise characteristics of semiconductor detectors, the maximum count rate of an ED system is usually no more than 30 000–50 000 counts per second, compared with in excess of  $10^6$  counts for a WD spectrometer, acting as a single channel analyzer. The reason is the relatively long count time constant that must be selected for ED preamplifier circuits (typically 6  $\mu$ s), compared with  $<1$   $\mu$ s for counter preamplifiers used on WD spectrometers. As a consequence, equivalent analytical precision can only be achieved by extending ED spectrum count times to a significant extent compared to WD.

5. As ED spectra are stored in digital form, more sophisticated procedures are available to correct for background contributions and overlap interferences than WD.

6. Because ED detectors 'see' the entire spectrum, optimization of analytical programs is not just a question of maximizing sensitivity for the elements of interest. Consideration must be given to maximizing detection capabilities to the 'region', which contains the element lines of interest so the finite spectrum processing capacity is not wasted on other spectral regions that contain little or no useful analytical information.

At one time, ED applications were often more limited than those of WD-XRF instruments, and were not used as extensively for high-precision quantitative analysis. However, following developments in semiconductor detector technology and in the speed and stability of digital processing electronics, this distinction is no longer as valid. Because of the versatile way in which ED-XRF can be configured, ED has become the instrument of choice in a large range of quantitative applications, particularly those where state-of-the-art precision or detection limit capability is not a fitness-for-purpose criterion.

## ED-XRF Excitation Configurations

The instrumental configurations most commonly used in ED-XRF spectrometry can be categorized as follows.

### Direct Tube Excitation

In the simplest excitation configuration (comparable to that employed in the majority of WD-XRF instruments), the sample is excited directly by the output of an X-ray tube (Figure 1). Selective excitation can be achieved by judicious choice of tube anode, operating voltage, and the use of a primary beam filter (normally comprising a thin foil of metal or cellulose), placed between tube and sample to modify the energy distribution of the tube spectrum reaching the sample. In this way, effective excitation can be restricted to a particular region of the fluorescence spectrum, so maximizing utilization of the pulse processing capacity for detection of the group of elements of interest. Adequate excitation can normally be achieved using a maximum tube power of only 50 W.

Taking these factors into account, optimum excitation of elements below iron in the periodic table would normally be achieved using a tube potential of 10–15 kV with no primary beam filter (or alternatively a thin cellulose filter if determination of the lightest elements was not required). Conversely, higher atomic number elements determined from fluorescence lines above  $\sim 7$  keV would normally be excited at 30–50 kV using an appropriate metal foil as primary beam filter. As in conventional WD-XRF, the choice of tube anode is important in dictating the elements that may be detected with highest sensitivity. An example of a spectrum acquired for the measurement of the K-lines of trace elements rubidium, strontium, yttrium, zirconium, and niobium in geological samples using a silver anode X-ray tube in conjunction with a silver foil primary beam filter (in a combination sometimes known as a 'regenerative monochromatic' filter) is shown in Figure 2. The silver tube K-lines are efficient in exciting the element lines of interest. At the same time, the silver foil

attenuates the lower-energy tube continuum, so that matrix elements (specifically, K-lines of the elements up to iron in the periodic table) are not excited effectively and do not, therefore, compete for detection capacity (region A in Figure 2). Furthermore, although the attenuation properties of the silver foil allow efficient transmission of the silver tube K lines, lower-energy tube continuum radiation in the region of the trace element lines of interest is attenuated to a significant extent, so reducing the background contribution from scatter off the sample (region B in Figure 2). Using this excitation strategy, together with a count time extended up to 1200 s, detection limits can be achieved for the specified trace elements in the range 1–2  $\mu\text{g per g}$ . In this way, direct tube excitation offers a flexible and sensitive method for the selective excitation of a wide range of elements for quantitative or qualitative analysis.

### Secondary Target Excitation

In a secondary target ED-XRF instrument, the sample is excited by characteristic fluorescence radiation from an elemental 'target', which is itself excited by an X-ray tube (Figure 3). This configuration offers the advantage of selective excitation of the group of element lines that have critical excitation energies immediately below the energy of the characteristic fluorescence lines from the secondary target. By exchange of secondary target, the instrument can be 'tuned' to measure different ranges of elements with high sensitivity. Performance may be further enhanced by use of a primary beam filter between X-ray tube and secondary target fulfilling a role similar to that described in the previous section.

The range of secondary targets installed on a typical instrument and their element ranges is shown in Table 1. Although secondary targets of high atomic

**Figure 1** Schematic view of an ED-XRF instrument incorporating direct tube excitation showing X-ray tube, primary beam filter, sample, and Si(Li) ED detector.

**Figure 2** ED-XRF spectrum of a granitic rock excited with a silver anode X-ray tube at 40 kV, comparing a spectrum recorded by unfiltered direct excitation with one recorded with a 127  $\mu\text{m}$  silver foil filter placed in the primary X-ray beam. Spectra have been offset and are plotted using a logarithmic intensity scale. The effect of the silver filter is as follows: (1) suppression of fluorescence of the major elements (region A); (2) enhancement of peak-to-background ratios for geochemically interesting trace elements (region B); and (3) selective attenuation of the higher-energy tube continuum (region C).

**Figure 3** Schematic view of an ED-XRF instrument configured for secondary target excitation. The tube–secondary target–sample–detector path is designed to have a Cartesian arrangement to suppress scatter of tube radiation into the detector.

number metals (e.g., gadolinium, silver) can be used to excite a relatively wide range of elements, the converse is true of lower atomic number targets (e.g., iron and titanium). These characteristics result from the way in which the mass attenuation properties of elements vary with energy. For the efficient determination of the lowest atomic number elements (in

particular below about potassium in the periodic table), direct tube excitation is often used.

A further advantage of secondary target excitation geometry is the reduction in background that can be achieved if the instrument is designed with a Cartesian X-ray optical configuration between tube–target–sample–detector, as shown in **Figure 3**. After scatter off the secondary target, radiation from the X-ray tube is polarized at right angles to a plane passing through the tube, target, and sample. In theory, this polarized radiation cannot be scattered a second time off the sample in the direction of the detector providing the Cartesian arrangement is employed. As a consequence, the intensity of the ‘Barkla’ scattered background (which is one of the limitations in the detection limit performance of any XRF instrument) is reduced significantly. However, to ensure adequate excitation intensities, most secondary target instruments are designed with close coupling between the various components so that the ideal Cartesian performance is reduced by a solid-angle-effect. The degree of polarization is also reduced by multiple scatter of X-ray photons in the target or sample. Even so, secondary target instruments offer flexible operating characteristics in exciting elements to best detection limits in the

1–5 µg per g range. Most efficient use of instrumentation is in the determination of groups of elements that can be excited efficiently by one or two secondary targets, since comprehensive elemental analysis would require sequential measurement of spectra using a number of secondary targets, together with direct tube excitation for the lightest elements. A further development of this geometric arrangement is to substitute targets made of low atomic number material to scatter the tube spectrum, a polarized excitation geometry that is discussed further below.

### Radioisotope Excitation

In view of the efficient detection capabilities of the ED detector, effective XRF measurements can be made with a suitable radioisotope source of moderate activity, despite the lower photon intensity that is likely to be available in comparison with an X-ray tube. To cover the full analytical range, four radioactive isotopes are available: <sup>55</sup>Fe (which emits Mn K-line X-rays at 5.9 and 6.5 keV), <sup>244</sup>Cf (14.3–21.4 keV, Pu L-line X-rays), <sup>109</sup>Cd (22.2–25.5 keV Ag K-line X-rays), and <sup>241</sup>Am (59.5 keV γ-emission). Depending on the application, instruments may be designed with a single source often mounted in an annular configuration to maximize excitation and detection efficiencies (Figure 4), or alternatively with different sources mounted on a carousel to facilitate sequential excitation of samples. In contrast to the instrumentation described in the previous sections, radioisotope excitation offers little scope for changing excitation characteristics (other than by exchange of source). However, with no requirement for a tube power supply, instrumentation is potentially cheap and simple to operate and has found particular use in two areas:

1. Specific applications in the laboratory or factory environment that cannot readily be satisfied by other techniques; for example, the determination of sulfur in oil or chlorine in brines and liquors (competitive techniques based on optical emission, for example, are often insensitive to the electronegative elements).
2. Instruments in which a portable excitation and analysis unit can be used for the field measurement of environmental contamination (e.g., measuring the distribution of heavy metals in soil at an industrial site) or in mineral exploration applications where the ability to analyze a sample directly in the field cannot be rivaled by competitive techniques. In some applications, particularly for the analysis of simple matrices where special overlap interferences do not present a problem, a proportional counter can be used as the ED detector. Although offering poor

spectral resolution, these latter devices are less expensive, robust, and do not require cooling.

### Total Reflection XRF Spectrometry

Total reflection XRF instruments (see **Figure 5**) are based on the principle that when an X-ray beam strikes an optically flat surface at grazing incidence (i.e., at below the critical angle), the beam will suffer total reflection from the surface, in theory, without absorption or scatter. In these circumstances, a thin sample deposited on the surface will be selectively excited with considerable suppression of the background component, which would otherwise result from scatter events in the substrate. This specialized XRF configuration incorporates ED

technology and is described in detail elsewhere in this encyclopedia.

### ED-XRF Using Polarized Excitation

Low atomic number materials are more efficient at scattering X-rays than higher atomic materials. If, therefore, the metal target (in the secondary target ED-XRF configuration, **Figure 3**) is replaced by a low atomic number target such as boron carbide (or corundum), the benefits of polarization can be achieved, without interference from nonpolarized secondary target lines. The entire tube spectrum is polarized by the low atomic number secondary target and is available to excite the sample, but this polarized beam cannot (in an ideal geometric arrangement) be scattered off the sample into the detector. This arrangement offers the benefits of direct tube excitation but using a polarization configuration that suppresses the detection of scattered tube background. Instruments of this design are capable of achieving detection limits in the range 1–5  $\mu\text{g per g}$  in the analysis of environmental samples. To compensate for intensity losses during the excitation process, the primary excitation source must be a higher power X-ray tube (e.g., 1–2 kW).

A second process is capable of achieving a similar effect, but instead based on Bragg diffraction at  $90^\circ$ . A few combinations of X-ray tube lines and crystalline materials cut at a particular orientation display the property of Bragg diffraction through a  $2\theta$  angle of  $90^\circ$ . Polarization is inherent in the diffraction process, so that the overall benefit in this arrangement is similar to the Barkla scatter process. However, diffraction is a more efficient process than scatter, so that the Bragg diffraction of Pd L-lines from a particular orientation of a highly orientated pyrolytic graphite crystal provides a significant boost to the excitation of the low atomic number elements (Na to Cl K-lines).

**Figure 4** Radioisotope ED-XRF instrument showing configuration of annular source, sample, and detector. The X-ray detectors used in this application include Si(Li) and  $\text{HgI}_2$  semiconductor detectors and gas proportional counters, the latter being favored for element-specific laboratory applications.

**Figure 5** Total reflection XRF instrumentation showing the arrangement of X-ray tube, reflectors, and ED detector. The sample is normally prepared by evaporating a sample solution onto the appropriate quartz reflector plate.

### Synchrotron Radiation XRF (SXRF)

The synchrotron is a highly specialized radiation source used to generate high intensity, near parallel, polarized beams of X-rays. These beams can be configured to undertake XRF measurements of samples in a number of ways and a general arrangement is shown in Figure 6. In a more specialized X-ray microprobe configuration, the beam is focused by reflection or diffraction off appropriate X-ray mirrors. Because of the high intensity and polarized nature of this X-ray source, the SXRF microprobe is capable of achieving very low detection limits for some elements in the submicrogram per gram range. This technology and its analytical capabilities are described in more detail elsewhere in this encyclopedia.

### ED-XRF Instrumentation

The particular aspects of ED-XRF instrumentation that facilitated the development of the above forms of instrumentation and give the technique its distinctive analytical characteristics are as follows.

#### Semiconductor Detector

Semiconductor technology is still a rapidly developing field that has seen the introduction of new detector types in recent years. However, the standard detector type on which ED-XRF technology was founded is the lithium-drifted silicon detector, Si(Li). This is the detector type against which the performance of new types of semiconductor detector is evaluated.

The Si(Li) detector crystal is made from high-purity silicon. Lithium atoms are drifted into its lattice structure to compensate for undesirable electronic properties caused by the presence of impurity

atoms. The detector crystal is normally machined in the form of a 'grooved disk' profile of thickness  $\sim 3\text{--}5\text{ mm}$  and active cross-section  $10\text{--}50\text{ mm}^2$  mounted inside a detector housing, which is maintained under high vacuum and is fitted with an entrance window made of beryllium foil (Figure 7). X-ray photons interact with the crystal and cause ionization from the valence to conduction bands. The small electronic charge formed by this process is proportional to the energy of the detected X-ray photons. This charge is collected by applying a bias of 500–1000 V across the detector crystal and amplifying it using a high-gain field-effect transistor (FET) prior to further amplification and pulse processing.

Each detected event creates a relatively small electronic charge that must be distinguished from the inherent electronic noise in the detector crystal. To maximize the signal-to-noise ratio, design features of Si(Li) spectrometers include:

1. Cooling the detector crystal, preferably to liquid nitrogen temperatures, to minimize thermal noise contributions to the detected electronic signal.
2. Use of a low-noise, high-gain FET mounted in the vacuum housing adjacent to detector crystal (to minimize contributions from stray electronic noise) as the first stage of signal amplification.
3. Selection of a relatively long time constant for the integration of the detected signal in the main pulse processing amplifier.

With these features, the overall resolution of a Si(Li) detector and pulse processing system used in XRF applications measured as the full-width at half-maximum (FWHM) of the Mn K- $L_{2,3}$  ( $K\alpha$ ) line at 5.9 keV is typically 140–155 eV (noting that <120 eV FWHM is technically feasible).

**Figure 6** Synchrotron radiation-induced X-ray fluorescence instrumentation showing, schematically, the arrangement of sample and detector in an experimental enclosure placed at the end of a synchrotron beam line.

**Figure 7** Cross-sectional diagram of an ED detector showing an Si(Li) detector crystal and associated FET mounted at the end of a copper cold finger inside an evacuated housing. The detector housing is fitted with an entrance window normally made of beryllium foil.

These detection characteristics apply to other semiconductor detectors, which do, however, possess other response characteristics. For example, germanium X-ray detectors are very similar in design to Si(Li) detectors but theoretically have better energy resolution (down to  $\sim 120$ – $140$  eV FWHM at  $5.9$  keV in XRF applications), but more importantly, higher stopping power to higher-energy fluorescence X-rays (because of the higher atomic number of Ge compared with Si). Germanium detectors offer positive benefits in the detection of the spectrum region above  $20$  keV where the detection efficiency of Si(Li) starts to fall off markedly. Exploitation of this application would normally require the use of a  $100$  kV X-ray tube (or  $^{241}\text{Am}$  excitation source) to excite the K-lines of the heavier trace elements. Mercury(II) iodide is a semiconductor material that has also been developed for this higher-energy fluorescence spectrum application. This detector type has the advantage of operating satisfactorily with a low degree of Peltier cooling (rather than requiring liquid nitrogen cryogenic cooling), and offers an energy resolution of down to  $\sim 185$ – $200$  eV FWHM. Cadmium–zinc–telluride (CZT) has also been developed for this application; however, its use is currently more experimental than for routine applications. The most influential recent developments have been the silicon-PIN diode (Si-PIN) and the silicon drift detector. Both detector types have the advantage of being non-cryogenic (Peltier cooling only). Both are currently fabricated typically as wafers  $300\text{ }\mu\text{m}$  thick and so are optimized for detection of the  $0$ – $20$  keV region of the X-ray spectrum (detector efficiencies of  $300\text{ }\mu\text{m}$  wafers start to drop off significantly above  $15$ – $20$  keV) and both offer resolutions that approach or are better than  $180$  eV (at  $5.9$  keV). The Si-PIN diode operates by detecting the electronic charge created by the interaction of an X-ray photon with the photodiode material. To achieve adequate resolution (currently better than  $\sim 180$ – $200$  eV FWHM at  $5.9$  keV), the detector signal processing electronics must be operated at a relatively large time constant (e.g.,  $6$ – $20\text{ }\mu\text{s}$ ).

This restricts the total count rate capability of the detector system to  $2000$ – $10\,000$  cps. The Si-drift detector has an active area of  $5$ – $10\text{ mm}^2$  and wafer thickness of  $300\text{ }\mu\text{m}$ . The design offers an intrinsically low capacitance, meaning that the detector is capable of retaining its performance even at high count rates ( $10^6$  cps has been achieved with these devices under experimental conditions). Current designs offer resolutions down to  $\sim 140$  eV and, although expensive to fabricate, are also noncryogenic (requiring modest Peltier cooling) and have significant future potential in ED-XRF applications.

In very simple instruments, gas proportional counters can be used as ED detectors. However, their intrinsic resolution of  $\sim 1000$  eV at  $5.9$  keV limits applications to those where significant spectral overlap interferences are not anticipated. At the other extreme, research is currently being undertaken to develop microcalorimeter detectors that must be cooled to a spectacularly low temperature in the millikelvin range to achieve a spectacularly high resolution in the electron-volt range. Not surprisingly, these devices are a long way away from being used in routine applications.

## Pulse Processing Electronics and Dead Time

When considering the operating characteristics of Si(Li) detectors, amplifier time constants of up to  $30\text{ }\mu\text{s}$  are required to distinguish the signal originating from low-energy photon events from the ambient electronic noise component of ED detectors (compared with a value of less than  $1\text{ }\mu\text{s}$  used for WD-XRF proportional counter signal amplifiers). This requirement has the undesirable effect of limiting the maximum data acquisition rate of the ED spectrometer. Furthermore, the electronic design of pulse recognition, shaping, and amplification circuitry requires careful consideration to optimize performance in this application. Each time an X-ray photon is detected, the input circuits of the pulse

processor must effectively be switched off whilst the current event is being measured. Any events that would have been detected during this 'dead time' interval are essentially unrecorded. To compensate for discrepancies that would occur in the comparison of spectra recorded at different count rates, the spectrum acquisition time must be extended by an amount that will compensate for this 'dead time' effect. In view of the long time constants that must be selected, ED spectrometers cannot normally operate at an output count rate of more than 3000–30 000 cps (depending on circuit design) and would routinely be operated at data acquisition rates corresponding to a dead time of 20–40%. A further problem arises at higher data acquisition rates when there is an increase in the probability of the near-coincident detection of two separate X-ray events. If these events occur within a limiting time interval of a few microseconds, the pulse processor circuits cannot distinguish the separate events. As a result, a sum peak caused by this 'pulse pile-up' event is recorded and appears in the spectral output. This artifact is usually most significant in spectra recorded at high count rates.

## Spectral Artifacts

Spectral artifacts are peaks that are not present in the source fluorescence spectrum but result from idiosyncrasies in the response of the detector and pulse processing system (such as the sum peaks referred to above). Their presence can cause ambiguities in the

qualitative interpretation of ED spectra or errors in quantitative analysis if mistaken for genuine fluorescence lines. Typical artifacts are illustrated in the spectrum recorded using an Si(Li) detector from a radioactive  $^{55}\text{Fe}$  source, which emits Mn K- $L_{2,3}$  ( $K\alpha$ ) and Mn K- $M_{2,3}$  ( $K\beta$ ) radiation, but no continuum (Figure 8). The principal features of this spectrum are as follows:

1. Peaks at 5.9 and 6.5 keV, originating from 'photoelectric detection' of Mn K- $L_{2,3}$  ( $K\alpha$ ) and Mn K- $M_{2,3}$  ( $K\beta$ ), broadened by the statistical factors that affect the detection process as discussed above.
2. 'Escape peaks', which occur when a detected X-ray photon fluoresces silicon atoms in the detector crystal. A small proportion of the resultant Si K-line photons are likely to escape out of the detector rather than be absorbed within the crystal and so represent an apparent loss in detected energy from the parent photon. This phenomenon causes an artifact peak to appear at an energy of 1.78 keV (the energy of the Si K line) below the parent event.
3. 'Sum peaks' corresponding to pulse pile-up of (Mn K- $L_{2,3}$  ( $K\alpha$ ) + Mn K- $L_{2,3}$  ( $K\alpha$ ), (Mn K- $L_{2,3}$  ( $K\alpha$ ) + Mn K- $M_{2,3}$  ( $K\beta$ ), and (Mn K- $M_{2,3}$  ( $K\beta$ ) + Mn K- $M_{2,3}$  ( $K\beta$ )), caused by the inability of the counting system to resolve near-coincident X-ray events, as described in the previous paragraph. Sum peaks are only likely to be of significance when operating at high count rates or when searching for trace elements in a spectrum dominated by major element lines.

**Figure 8** Spectrum of an  $^{55}\text{Fe}$  source (which emits K X-rays) recorded on a Si(Li) ED detector showing spectrum artifacts, including sum peaks and escape peaks. The same spectrum is displayed on both logarithmic and linear intensity scales to show both minor spectral features as well as relative intensities.

4. An 'enhanced background' at photon energies below the fluorescence lines, resulting from incomplete charge collection in the detector crystal. A small fraction of the electronic charge that results from the detection of Mn K-L<sub>2,3</sub> (K $\alpha$ ) and Mn K-M<sub>2,3</sub> (K $\beta$ ) events may be trapped in the crystal lattice so that the detected event contributes in a random manner to the background at energies below the parent peak.

These artifacts must be taken into account in the visual interpretation of ED-XRF spectra and in the spectrum analysis procedures used for quantification of peak areas.

In principle, these detector artifacts are found in other silicon-based detectors (although the relative severity will vary with detector design) and in detector types made of other materials (although some characteristics, such as escape peak energies will be different, depending on the composition of the detector).

## Spectrum Deconvolution

In view of the resolution characteristics of an ED detector, spectral overlap interferences are much more common in ED-XRF than WD-XRF and require a more comprehensive correction procedure than the simple line ratio method often used in the latter technique. However, advantage can be taken of the digital form in which ED spectral data are accumulated in the multichannel analyzer, which offers information about peakshapes as well as intensity. For simple ED spectra, it may be possible to define a series of 'windows' covering each fluorescence peak of interest (the 'region-of-interest' approach). Peak intensities can then be determined by channel integration and a background correction applied by linear interpolation between the lowest and the highest channel of the window. For complex spectra, a more sophisticated approach is required, of which two have found widespread use.

### Background Modeling with Peak Fitting

The background continuum of the fluorescence spectrum can be modeled by fitting a curve derived from Kramer's equation, which has the general form:

$$I = kZ[(E_0 - E)/E]$$

where  $I$  is the continuum intensity at photon energy  $E$ ,  $E_0$  is the energy equivalent to the X-ray tube operating potential,  $Z$  is the mean atomic number of the matrix, and  $k$  a constant. Having corrected for the background continuum using this approach, the area of residual photopeaks (and hence X-ray line intensities) may be calculated by peak fitting, using a

Gaussian or modified Gaussian function. To perform this fitting successfully, the variation of FWHM of the detector as a function of energy must be precalibrated accurately, as must the intensity of the K-M<sub>2,3</sub> (K $\beta$ ) relative to the K-L<sub>2,3</sub> (K $\alpha$ ) line so that the calculated area of the former can be subtracted from the spectrum to compensate for spectral overlap influences.

### Digital Filtering

An alternative approach involves the use of a 'digital filter' to remove the background component of recorded spectra. The digital filter is a simple algebraic function that distinguishes the continuum component of the spectrum from X-ray peaks, normalizing the former to zero. During this transformation, the ED spectrum is convoluted to a form that resembles the negative of the second derivative. Photopeak intensities can then be quantified by fitting, using a least-squares minimization procedure, library spectra of individual elements that have also been convoluted by the same digital filter function. To operate successfully, any drift in spectrum origin and gain must be corrected accurately. This procedure offers a degree of automatic spectral overlap correction and allows quantification of spectral data that show apparently serious overlap interferences involving both K- and L-lines.

## Applications and Operating Practice

Some of the more specialized applications of ED-XRF instrumentation have been summarized in previous sections. Further examples, mainly relevant to direct tube and secondary target excitation using Si(Li) detectors, are summarized here.

### Qualitative Analysis

It has already been mentioned that ED-XRF offers unrivalled performance in qualitative analysis, the only real restrictions being that samples should preferably (though not exclusively) be in a solid form and have a size and shape that can be accommodated in the sample chamber. The other main limitation is that the technique is insensitive to elements of atomic number lower than sodium in the periodic table. Since X-ray spectra can normally be interrogated during data acquisition, experienced operators can usually identify the sample matrix from its principal XRF lines within a few seconds. However, if identification depends on the presence of trace elements, ED-XRF data acquisition times may have to be extended substantially and it may then be beneficial to analyze the sample on a WD-XRF instrument to take

advantage of the higher spectral resolution available when scanning the WD spectrometer.

Qualitative ED-XRF analysis is often most effective when the application involves comparing the spectrum of a sample with that from a material of known composition. Differences in composition are then simple to identify visually. This capability, together with the nondestructive nature of ED-XRF, is important in the analysis of museum artifacts and forensic samples. For example, forensic glass fragments can be fingerprinted by ED-XRF on the basis of variations in key elements to distinguish their origin (e.g., vehicle glass versus plate glass versus milk bottle glass). However, such applications are often only fully effective when based on semiquantitative analytical results. The relative intensity of X-ray peaks observed during ED-XRF analysis gives the operator a visual identification of the relative concentration of elements present. However, interpretation cannot be definitive without some form of matrix correction that can be undertaken simply by using the fundamental parameter approach with an appropriate normalization to account for irregular sample geometries. One application of semiquantitative ED-XRF is in alloy sorting, where subtle differences in elemental data from semiquantitative analysis be used to identify the type of alloy (Figure 9).

### Quantitative Analysis

For the highest accuracy, sample presentation must be reproducible, and for this reason, requirements for

**Figure 9** Comparative ED spectra in an alloy sorting application. By rapid ED-XRF analysis for Ni, Cr, Co, Fe, and Ti, these samples can be distinguished as the nickel-based alloys, Nimonic 90, 80, and 75. For convenience, spectra have been normalized to show equivalent Ni K-line intensities. (Spectrum courtesy of AT Ellis, Oxford Instruments.)

the preparation of samples in the form of flat disks of metal, compressed powder pellets, or glass disks are no different from those specified for WD-XRF analysis. However, differences in analytical programs for quantitative analysis by ED-XRF, including (1) instrumental conditions must be optimized to excite selectively regions of the spectrum of analytical interest (as discussed above), and (2) count times for spectrum acquisition must be extended to 500–1200 s to attain adequate precision. In routine schemes of analysis, the precision and detection limits for the lower atomic number elements (particularly between sodium and iron in the periodic table) are not normally as good as those attainable by WD-XRF, because of inferior spectral resolution, additional attenuation of the lower-energy fluorescence spectrum in the beryllium window fitted to the ED detector, and the lower data acquisition rates. However, these restrictions are not as significant in the determination of trace elements in the 10–20 keV region of the spectrum, where ED-XRF results for some elements from an 800–1200 s acquisition time are likely to be comparable with those expected by routine WD-XRF. A comparison of detection limits expected in geological applications is given elsewhere in this encyclopedia.

### Field Analysis

One application where ED-XRF instruments offer exciting potential is in the analysis of samples *in situ* using field-portable instrumentation, based on excitation using radioisotope sources, or more recently miniature X-ray tubes. Such instrumentation facilitates applications that cannot readily be undertaken by other techniques, including the characterization of heavy metal contamination in soils at industrial sites, the nondestructive analysis of large artifacts at archaeological sites, and on-site assessment of environmental hazards from operations such as stripping leaded paint.

### Introduction

Total reflection X-ray fluorescence (TXRF) spectrometry is a trace elemental microanalysis technique based on conventional energy dispersive X-ray fluorescence. It has become increasingly popular in the last decade and is applied in almost every field of trace elemental analysis where low detection limits and multielement capabilities are required. Like all X-ray techniques, TXRF is nondestructive making it extremely useful and important in areas where samples are precious and/or need to be used for further characterization. New tabletop instruments make this technique affordable and more versatile as it can be used also for field research. In the semiconductor industry, TXRF is now routinely applied to scan wafers for impurities on the surface and in near-surface layers. The following article introduces the basic principle of TXRF and its instrumental features and discusses various applications of this technique.

### Basic Principles

#### Total Reflection, Reflectivity, and Penetration Depth

When an X-ray beam strikes the surface of a solid medium at a certain angle  $\varphi$  it can be refracted or reflected. According to Snell's law the refractive indices  $n$  of two media 1 and 2 are in the following relationship:

$$n_1 \cos \varphi_1 = n_2 \cos \varphi_2 \quad [1]$$

In case absorption has to be considered the refractive index  $n$  consists of a real part  $\delta$  and an imaginary part  $i\beta$ . The real part refers to the decrement of dispersion and the imaginary part to the attenuation:

$$n = 1 - \delta - i\beta \quad [2]$$

For X-rays, both  $\delta$  and  $\beta$  are zero in vacuum or air, but slightly positive for solids. Thus, any solid

medium does have a refractive index  $n$  smaller than one and is optically less dense than air (vacuum). Therefore, the refracted beam will be deflected toward the medium boundary and a critical angle will exist at which total reflection of the X-ray beam occurs. Using Snell's law (1), the critical angle  $\varphi_c$  can be calculated for a medium of known composition by using eqn [3]:

$$\varphi_c = \sqrt{(2\delta)} = (1.65E^{-1})\sqrt{ZA^{-1}\rho} \quad [3]$$

where  $E$  is the energy in keV,  $A$  the atomic mass in  $\text{g mol}^{-1}$ ,  $Z$  the atomic number, and  $\rho$  the density in  $\text{g cm}^{-3}$ . At the critical angle the reflectivity  $R$  of the material increases to almost 100% and the penetration depth  $z_p$  of the primary beam decreases drastically to only a few nanometers. Calculation of the reflectivity  $R$  can be done for any material by using the Fresnel formula. The penetration depth  $z_p$  refers to the depth at which the intensity of the primary beam decreases to  $e^{-1}$  or 37% of its initial value. Below the critical angle the reflectivity remains high and the penetration depth low. However, once the critical angle is exceeded both change, with penetration depth increasing and reflectivity decreases rapidly. The very low penetration depth of the incident beam at and below the critical angle makes TXRF spectrometry well suited for analysis of matter deposited on and embedded in the uppermost layers of a solid medium.

In Table 1, critical angles, reflectivity, and penetration depth of some common materials used in total reflection X-ray analysis are summarized for an excitation energy of 17.44 keV, corresponding to Mo K excitation. The table shows that the reflectivity for materials composed of light elements is high, but decreases for heavier elements. In the latter case, absorption effects become more prominent and affect the reflectivity negatively.

#### Standing Waves

TXRF is intimately connected to a standing wave field created by interference of incident and total

### Introduction

Total reflection X-ray fluorescence (TXRF) spectrometry is a trace elemental microanalysis technique based on conventional energy dispersive X-ray fluorescence. It has become increasingly popular in the last decade and is applied in almost every field of trace elemental analysis where low detection limits and multielement capabilities are required. Like all X-ray techniques, TXRF is nondestructive making it extremely useful and important in areas where samples are precious and/or need to be used for further characterization. New tabletop instruments make this technique affordable and more versatile as it can be used also for field research. In the semiconductor industry, TXRF is now routinely applied to scan wafers for impurities on the surface and in near-surface layers. The following article introduces the basic principle of TXRF and its instrumental features and discusses various applications of this technique.

### Basic Principles

#### Total Reflection, Reflectivity, and Penetration Depth

When an X-ray beam strikes the surface of a solid medium at a certain angle  $\varphi$  it can be refracted or reflected. According to Snell's law the refractive indices  $n$  of two media 1 and 2 are in the following relationship:

$$n_1 \cos \varphi_1 = n_2 \cos \varphi_2 \quad [1]$$

In case absorption has to be considered the refractive index  $n$  consists of a real part  $\delta$  and an imaginary part  $i\beta$ . The real part refers to the decrement of dispersion and the imaginary part to the attenuation:

$$n = 1 - \delta - i\beta \quad [2]$$

For X-rays, both  $\delta$  and  $\beta$  are zero in vacuum or air, but slightly positive for solids. Thus, any solid

medium does have a refractive index  $n$  smaller than one and is optically less dense than air (vacuum). Therefore, the refracted beam will be deflected toward the medium boundary and a critical angle will exist at which total reflection of the X-ray beam occurs. Using Snell's law (1), the critical angle  $\varphi_c$  can be calculated for a medium of known composition by using eqn [3]:

$$\varphi_c = \sqrt{(2\delta)} = (1.65E^{-1})\sqrt{ZA^{-1}\rho} \quad [3]$$

where  $E$  is the energy in keV,  $A$  the atomic mass in  $\text{g mol}^{-1}$ ,  $Z$  the atomic number, and  $\rho$  the density in  $\text{g cm}^{-3}$ . At the critical angle the reflectivity  $R$  of the material increases to almost 100% and the penetration depth  $z_p$  of the primary beam decreases drastically to only a few nanometers. Calculation of the reflectivity  $R$  can be done for any material by using the Fresnel formula. The penetration depth  $z_p$  refers to the depth at which the intensity of the primary beam decreases to  $e^{-1}$  or 37% of its initial value. Below the critical angle the reflectivity remains high and the penetration depth low. However, once the critical angle is exceeded both change, with penetration depth increasing and reflectivity decreases rapidly. The very low penetration depth of the incident beam at and below the critical angle makes TXRF spectrometry well suited for analysis of matter deposited on and embedded in the uppermost layers of a solid medium.

In Table 1, critical angles, reflectivity, and penetration depth of some common materials used in total reflection X-ray analysis are summarized for an excitation energy of 17.44 keV, corresponding to Mo K excitation. The table shows that the reflectivity for materials composed of light elements is high, but decreases for heavier elements. In the latter case, absorption effects become more prominent and affect the reflectivity negatively.

#### Standing Waves

TXRF is intimately connected to a standing wave field created by interference of incident and total

reflected beam near or at the critical angle. For a thick flat medium, superposition of two or more coherent and monochromatic X-ray beams leads to a triangular standing wave field with minima (nodes) and maxima (antinodes) in front of the medium. **Figure 1** shows such a standing wave field schematically in front of a thick substrate. For a reflectivity of  $\sim 100\%$ , the amplitude of an incoming and a total reflected wave can be subtracted to zero (nodes) or added to a maximum value (antinodes). Minima and maxima follow each other with a period of  $d_{\min/\max} = (\lambda/2)/\varphi$ . Here,  $\lambda$  is the wavelength and  $\varphi$  the angle of the incident beam. A layer or sample deposited on top of the thick flat substrate is subjected to this standing wave field and is excited to fluorescence in proportion to the wave field intensity. It is therefore important that the sample is positioned well inside the standing wave field to gain maximum fluorescence of the sample. In addition, the sample should be granular or uneven, otherwise total reflection might occur inside the deposit. Too large samples should be avoided as well because absorption effects might interfere.

When a thin enough layer is present on a thick substrate, an additional standing wave field can be

observed in the thin layer itself beside the one in front of the substrate. When these conditions are fulfilled it is possible to probe surface layers opening up the field for surface and thin layer characterization.

### Fluorescence Intensity of Samples Deposited on Top of a Substrate and Below the Surface

A sample deposited on a thick flat substrate is exposed to both the incident and total reflected beams. Since the reflectivity  $R$  is  $\sim 100\%$  below and at the critical angle, the fluorescence intensity  $I$  is almost doubled according to eqn [4]:

$$I = I_0(1 + R) \quad [4]$$

where  $I_0$  is the intensity of the incoming X-ray beam at glancing angles. For a granular residue, the fluorescence intensity is nearly constant below and at the critical angle. **Figure 2A** illustrates that case. The background signal for such a sample is very low as the incident beam only penetrates a few nanometers into the substrate and does not contribute significantly to the background signal. For example, for quartz, silicon, or Plexiglas the background signal is about six orders of magnitude smaller than for conventional X-ray fluorescence. This increase in fluorescence intensity is responsible for the high detection power and correspondingly low detection limits of TXRF.

In **Figure 2B**, the fluorescence intensity at different glancing angles for atoms embedded in a near-surface layer is shown. As seen the fluorescence intensity is clearly angle dependent and experiences a maximum at the critical angle. This feature can be used to probe surface layers at different angles around the critical angle and obtain useful information about their composition and thickness. It is important to note that the layer is nonreflective and homogenous in composition. The angle dependency of the fluorescence intensity permits depth profiling of layered structures as well. The instrumental set-up for these applications is slightly different then for samples deposited on the substrate as it requires a mechanism to change the incident angle in small steps. Surface layer characterization is pertinent in the semiconductor industry where contaminations on wafers have to be determined to avoid malfunction of devices.

**Table 1** Critical angles  $\varphi_c$ , reflectivity  $R$ , and penetration depth  $z_p$  at the critical angle for selected materials calculated for 17.44 keV (Mo K $\alpha$ ) incident beam energy<sup>a</sup>

Material	$\varphi_c$ (°)	$R$ (%)	$z_p$ (nm)

**Figure 1** Standing wave field above a thick flat substrate.  $\varphi$  refers to the grazing angle of the incident and total reflected beams.

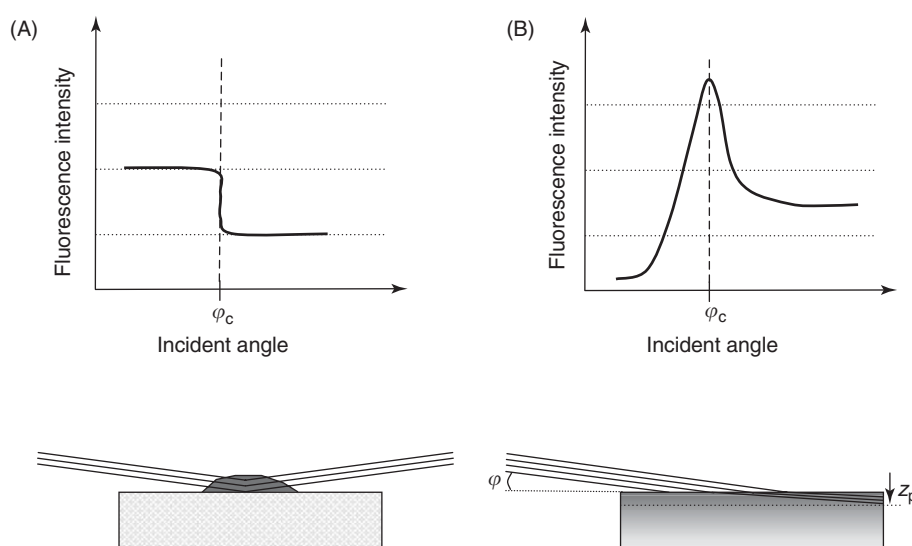

## Instrumentation

The general instrumental set-up for TXRF spectrometry is quite simple with an X-ray source, a reflector or monochromator, a second reflector, acting as sample support or sample itself, and a detector. A low pass filter to reduce the high-energy part of the X-ray spectrum has to be inserted in the path of the

primary beam to avoid a high background signal due to scattered photons. **Figure 3** shows such a basic instrumental set-up. Conditions for successful excitation of the sample under total reflection comprise a monochromatic well-collimated primary X-ray beam with a divergence of less than 0.2 mrad. The beam should be shaped like a strip of paper having a width of  $\sim 10$  mm and a height of  $10\text{ }\mu\text{m}$  to penetrate only a small area of the substrate. This is necessary because the detector has only a small window less than 1 cm in diameter. The beam can be shaped precisely by using slits or diaphragms in the optical path. When analysis of small deposits on a thick substrate is performed the incident angle should be less than the

critical angle of total reflection, i.e.,  $\sim 70\%$  of that angle. In most cases this corresponds to an incidence angle of  $\sim 0.06\text{--}0.07^\circ$  for the primary beam. In some special cases when light elements with atomic numbers less than 12 are of interest the optical path, including sample support (or second reflector), has to be under vacuum conditions. This translates to attaching the X-ray source and the detector with a flange to a vacuum chamber in which the sample and optics will be placed. A similar approach is used when working with synchrotron radiation as excitation source.

For surface analysis the instrument should be equipped with a mechanism permitting the variation

**Figure 2** Fluorescence intensity in dependency of the incident angle  $\varphi$ . For (A) a deposit on a flat thick substrate and (B) atoms present in a surface layer;  $z_p$  refers to the penetration depth of the incident beam.

**Figure 3** Basic set-up for a total reflection X-ray fluorescence spectrometer.

of the sample position in small steps around the critical angle of the incident beam.

### Excitation Devices

A high-intensity X-ray beam is necessary to excite the atoms in the sample to fluorescence. For trace- and microanalysis of deposits fine-focus X-ray tubes are sufficient, limiting already the size of the primary beam. Common anode materials are molybdenum, tungsten, or chromium, with molybdenum providing the widest energy range for elemental detection without change of the tube conditions. Chromium or scandium anodes are also recommended for detection of light elements in combination with a vacuum chamber. When performing surface analysis rotating anodes are required to satisfy the demand for lower detection limits. Rotating anodes show higher brilliance and better intensity, thus improving the detection power. In recent years, synchrotron radiation has become more easily available. Its high brilliance and polarization allows for extremely low detection limits. In addition, the energy of the incident beam can be tuned with a multilayer crystal. The instrumental set-up resembles closely the vacuum version, except that it has to be tilted by  $90^\circ$  owing to the polarization of the synchrotron beam in the horizontal plane. Several beam lines at different synchrotron facilities are now available for TXRF analysis.

### Monochromators

The polychromatic X-ray beam has to be monochromatized to be efficient in excitation of the sample. It is necessary to eliminate the high-energy part of the beam that would be scattered in the sample otherwise causing an increase in the background signal. In trace- and microanalysis a highly polished quartz prism is sufficient, cutting off the high-energy part of the spectrum under grazing incidence by acting as a total reflecting mirror. In addition, a thin metal foil can be inserted into the beam path acting as attenuator for certain energies. For surface and thin layer analysis the X-ray beam has to be strictly monochromatic to obtain good intensity profiles in dependency of the glancing angle. X-ray photons of different energies would interfere with this process and obstruct the angle scan. In this case natural crystals or multilayers are required as monochromatizing units. When natural crystals are used the spectral selectivity is higher but the intensity of the incident beam decreases. To compensate for the loss in intensity rotating anode devices have to be employed. Multilayers, on the other hand, show less spectral selectivity but permit for a higher intensity. One possibility to increase the selectivity for the latter set-up is the use of

two multilayers arranged in parallel position to guide the beam in a zigzag path toward the sample.

### Sample Positioning and Detectors

Utmost care has to be taken with respect to the sample positioning in a TXRF unit. Positioning of the sample needs to be extremely precise as the incident angle is very small, less than  $0.1^\circ$ . For trace- and microanalysis, a fixed sample position is realized with a precise positioning mechanism placing the sample exactly at the same spot for each analysis. In surface and thin layer analysis, sample positioning is even more crucial as the sample has to be moved with respect to the critical angle. For this the sample is deposited on a movable table, which can be rotated, tilted, and adjusted in the horizontal  $x,y$  direction in small steps. The sample support should be optically flat to permit total reflection of the primary beam. The surface roughness should be restricted to less than 5 nm and the waviness should not exceed  $0.001^\circ$ . The sample support has to be free of contamination and chemically inert when performing trace analysis. Materials meeting these requirements and most commonly used are quartz, Plexiglas or polycarbonate, glassy carbon, silicone, and sapphire. Some of them can be cleaned and reused for many analyses without loss in their properties. Detection of the spectra is carried out by Si(Li) detectors located directly on top of the sample at  $90^\circ$  angle and at a distance of a few millimeters. This ensures that the maximum amount of fluorescence radiation is captured by the detector and in addition minimizes the absorption of soft X-rays in the space between the detector and the sample. For analysis of light elements a high-purity germanium detector is recommended, having a better spectral resolution in the low-energy range.

### Analytical Performance

TXRF as a multielement microtechnique is capable of analyzing trace quantities or even ultratrace quantities in a sample. The sample has to be small with a mass of no more than a few micrograms and thin ( $\sim 10\text{--}15\ \mu\text{m}$  thickness) to permit penetration of the primary beam into the substrate for total reflection. Matrix effects are few or nonexistent due to the small sample size, thus eliminating absorption effects in the sample. In most cases, some sample preparation is required to obtain a homogeneous analyte and to restrict it in mass and size. Sometimes, however, a sample can be directly analyzed. This might be the case for homogenous powders of very fine grain sizes or thin sections of biological tissues. Owing to its

surface sensitivity TXRF can be applied for surface and thin layer analyses. This is of particular interest for determination of impurities or contaminations on wafers. In this case, variation of the glancing incident angle provides angle profiles of intensity levels. The detection limits are very low and comparable to most common analytical techniques used in atomic spectroscopy or surface characterization.

### Calibration and Quantification

Before quantitative analysis is possible the system has to be calibrated. For this, elemental profiles of each element are measured to obtain their net intensities. This includes preparing of single element standards with a concentration of  $1\text{--}10\ \mu\text{g l}^{-1}$  in ultraclean water and pipetting  $50\text{--}100\ \mu\text{l}$  of this solution on a sample carrier in several steps. The spectrum is recorded and added to the database. Such calibration needs to be done only once for each instrument as long as the components are not altered or exchanged in the equipment. More recent instruments are equipped with a software package enabling the calculation of the net intensities of peaks by using certain algorithms. This has the advantage that only few element profiles need to be measured.

Graphing of elemental concentration versus measured net intensity  $N$  shows a straight line with a slope representing the absolute sensitivity of this element. In Figure 4, intensities of some elements are shown. The relative sensitivity  $S_x$  for an element  $x$  is another important parameter and can be determined by the following equation:

$$S_x = (N_x c_x^{-1})(N_{\text{ref}} c_{\text{ref}}^{-1})^{-1} S_{\text{ref}} \quad [5]$$

where  $N_x$  and  $N_{\text{ref}}$  refer to the net intensity for element  $x$  and reference element (ref), and  $c_x$  and  $c_{\text{ref}}$  to the concentration of these. Since relative sensitivities are determined  $S_{\text{ref}}$  can be set to 1 by simplifying the calculation of the relative sensitivity for each element. It is also possible to obtain relative sensitivities mathematically without intensity measurements. Several factors are incorporated in the equation including fluorescence yield and relative emission rate. When elemental standards are not available for certain elements the relative sensitivity can be extrapolated or calculated by applying the above-mentioned equations.

Quantification is easy by adding an internal standard of known concentration to the sample either before sample preparation or when analyzing powder samples as a droplet on top of the powder. The internal standard consists of an element not present in the sample, often gallium or yttrium, sometimes germanium when the sample is present in basic solution, and should be somewhere in the medium concentration range of the elements to be determined. Care has to be taken when elements have to be quantified at ultratrace levels, which are located in the spectrum adjacent to the internal standard. Here the standard concentration should be as low as possible and in the best case adjusted to the expected element concentration to avoid peak shadowing. A 'blank run' without standard helps to estimate the concentration level of the element. When sample digestion is required the standard should be added before the digestion step to monitor losses. For powder samples the standard ought to be pipetted onto the sample itself and dried for analysis. Elemental concentrations can be

**Figure 4** Intensity profiles for selected elements (Mo K excitation, 20 ng amount). It can be seen that Ba and Ni overlap slightly.

calculated easily by using the following:

$$c_x = (N_x S_x^{-1})(N_{is} S_{is}^{-1})^{-1} c_{is} \quad [6]$$

where  $c_x$  and  $c_{is}$  refer to the concentrations of the element to be determined and the internal standard (known), respectively,  $N_x$  and  $N_{is}$  to their net intensities, and  $S_x$  and  $S_{is}$  to their relative sensitivities.

Calibrations in surface and thin layer analysis have to be performed differently by measuring external standards of pure elements, analyzing dried residues of a standard element, or after spin coating of a support or wafer with a spiked solution. Internal standardization is not suitable for quantification as angle variation of the glancing incident beam does alter the fluorescence intensity. Peak fitting and quantification has to be carried out by using the fundamental parameter method as known for conventional XRF spectrometry.

### Detection Limits

The detection limits for TXRF are significantly lower than for conventional XRF and comparable to most atomic spectrometric methods used for trace analysis or surface characterization. They range from several picograms to a few nanograms for the lighter elements in real samples and are somewhat lower for pure aqueous solutions. Improvement of detection limits is possible when the sample is pretreated and/or the matrix removed. This is particularly important

when analyzing organic, biological, or environmental samples. For surface contaminations the detection limits are  $\sim 10^9$  atoms  $(\text{cm}^2)^{-1}$  for transition metals by direct determination on the surface and can be improved to some  $10^7$  atoms  $(\text{cm}^2)^{-1}$  using special pretreatment techniques like vapor phase deposition. When synchrotron radiation is available as excitation source the detection limits can be decreased further for direct determination and are reported to be  $3 \times 10^8$  atoms  $(\text{cm}^2)^{-1}$  for Ni directly on a wafer. Table 2 shows the range of detection limits for commonly determined elements.

## Applications

The applications of TXRF spectrometry are manifold and frequently more are added. Table 3 summarizes applications in different fields. Generally, there are two types of applications: trace and microanalysis as well as surface and thin layer analysis. In both cases special care has to be taken so that sample preparation and/or analysis is done in very clean environments to avoid possible contamination.

### Trace- and Microanalysis

Almost any sample can be analyzed by TXRF spectrometry for its trace element content either directly or after some sample preparation steps. Such steps might include preconcentration, digestion, or matrix separation. Sometimes the samples do not need to be

**Table 2** Detection limits for commonly analyzed elements

pretreated but can be analyzed directly, which is the case for drinking or tap water, mineral waters, rain water, and even atmospheric particulates, when deposited directly on a reflector. An internal standard ensures quantification. Biological and medicinal materials generally need to be pretreated to remove the organic matrix that would increase the background signal and thus worsen the detection limits. Similar steps should be considered for environmental samples like soil or river and sea water. Microwave digestion with concentrated nitric acid or high-pressure digestion in specially designed polytetrafluoroethylene bombs are the most common pretreatment methods. When silicates are present in a sample some quantity of hydrofluoric acid can be added to ensure total dissolution. Oil samples can be diluted with a solvent or subjected to cold oxygen plasma ashing if necessary. In all cases the internal standard should be added before the sample preparation steps are performed to avoid errors due to element losses. Tissue samples can be analyzed as well when sliced with a microtome into small and thin sections and directly placed on the sample carrier or reflector. The general procedure of trace and ultratrace analysis is been summarized in **Figure 5**. With or without pretreatment the sample is deposited on the sample carrier either as a solid or as liquid in small droplet form of  $\sim 20\text{--}50\text{ }\mu\text{l}$  including the internal standard. For a solid sample the analysis can be performed directly whereas the liquid has to be dried either under infrared light or on a hot plate before analysis. Counting times range between 100 and 1000 s depending on the concentrations to be determined. **Figure 6** displays the spectrum of an atmospheric aerosol sample after microwave digestion with nitric acid. Here gallium was added as internal standard.

### Surface and Thin Layer Analysis

Surface analysis is possible when the samples are even and optically flat. Ideally suited for this are wafers as produced and used in the semiconductor industry. Both uncoated and coated wafers can be characterized. For uncoated wafers surface analysis is performed, whereas thin layer analysis is applied for coated wafers. In both cases intensity profiles in dependency of the incident angle around the critical one are recorded. This provides information about the elemental composition and thickness of the surface layer. When scanning at different locations of the wafer a surface map of the wafer can be obtained. In practice, some spots are selected and angle scans performed. It is possible to distinguish between different types of contamination – bulk, particulate type deposited on the surface, or thin layer type – on the wafer by comparing the shape of the angle scan with calibration samples. **Figure 7** shows these three types of contamination schematically. In thin layer analysis, layer parameter can be evaluated via iterative peak fitting procedures utilizing the angle scan. The detection limits for wafer analysis can be improved when the wafer is subjected to vapor phase decomposition (VPD) treatment. In this case the surface is slightly etched by hydrofluoric acid, and silica ( $\text{SiO}_2$ ) or silicon (Si) is removed as hexafluorosilicic acid ( $\text{H}_2\text{SiF}_6$ ). The reaction also produces water droplets in which the surface contaminants are trapped. These droplets are dried and analyzed by TXRF. Special chambers for VPD are usually employed.

### Recent Developments

Besides the more and more popular and accessible use of synchrotron radiation for TXRF, two variants

**Figure 5** General sample preparation steps for TXRF analysis.

**Figure 6** Spectrum of an urban aerosol sample taken in Chicago. Gallium was added as internal standard with the concentration of  $100 \mu\text{g l}^{-1}$ .

**Figure 7** Intensity profiles for different types of contaminations: (A) particulate type deposit; (B) thin film type deposit, and (C) bulk substrate.

of the technique have emerged in the recent years. One is grazing exit X-ray fluorescence (GE-XRF) and the other grazing incidence and exit X-ray fluorescence (GIE-XRF). In GE-XRF, the instrumental setup has been flipped, having a  $90^\circ$  incident angle, but employing a grazing take-off or exit angle. In GIE-XRF, both angles, the incident and the take-off angle of the beam, are grazing or close to zero. GE-XRF is often employed for nondestructive surface and thin layer analysis in combination with synchrotron radiation. It has certain advantages

compared to traditional TXRF like permitting a polychromatic incident beam with a lateral resolution of  $\sim 10 \mu\text{m}$ . Surface mapping becomes much faster and easier. In addition, a wavelength dispersive detector can be used which has a higher spectral resolution and thus shows a better peak separation. The disadvantage is that absorption effects can occur and matrix effects make quantification difficult. GIE-XRF is less common and more complicated to set up, but has the advantage that both the incident and the take-off angles can be adjusted. This allows for analysis of thin films and vertical concentration profiles.

## Particle-Induced X-Ray Emission

**W Maenhaut**, Ghent University, Ghent, Belgium

© 2005, Elsevier Ltd. All Rights Reserved.

### Introduction

Particle-induced X-ray emission (PIXE) is an elemental analysis technique that employs a beam of energetic heavy charged particles (usually protons of 1–4 MeV) to induce element-specific X-ray emission. Depending on the sample material and thickness and on the conditions of the analysis, the technique offers detection limits at the  $0.1\text{--}10\text{ mg kg}^{-1}$  concentration level for low- $Z$  matrices. Applied in nuclear microprobes, micro-PIXE combines a high sensitivity with the possibility of providing elemental maps with a lateral resolution in the sub-micrometer range.

### Basic Principles

PIXE was introduced in 1970, combining two technical developments into a novel variant of X-ray emission analysis with interesting capabilities. One innovation was the use of lithium-drifted (Si(Li)) detectors, which allow the simultaneous detection of the X-ray intensities of (nearly) all elements in the sample. The other novelty was that X-ray emission was induced by a proton beam of MeV energy instead of by an electron beam or bremsstrahlung radiation from an X-ray tube. The proton beam ejects inner-shell electrons from the atoms in the bombarded specimen (sample), the resulting vacancies are virtually instantaneously filled by outer-shell electrons, and this de-excitation process gives rise to the emission of X-rays whose energies are characteristic for the excited elements. Although the excitation mechanism is analogous to that in the electron microprobe, the much smaller deceleration of the protons (or other ions) in the specimen leads to a much lower bremsstrahlung continuum. The typical PIXE spectrum shown in Figure 1 consists of

characteristic X-ray peaks superimposed on a continuous background. Whereas the former result from the de-excitation of inner-shell vacancies, the background arises from several processes, especially secondary electron bremsstrahlung (SEB).

When a beam of heavy charged particles of a few MeV penetrates into matter, it loses its energy gradually with depth, until it is finally stopped. The energy loss occurs mainly through inelastic Coulomb interactions with bound electrons and in contrast to the case of electron beams, the direction of travel of an ion beam is scarcely altered during the slowing down process. The stopping power  $S(E)$  of an ion with energy  $E$  is defined as the energy loss per unit mass thickness traversed:

$$S(E) = -\frac{1}{\rho} \frac{dE}{dx} \quad [1]$$

where  $\rho$  is the density of the stopping material and  $x$  the distance. As defined here,  $S(E)$  is expressed in  $\text{keV g}^{-1} \text{cm}^2$ . The total path length  $R$  for an ion with incident energy  $E_0$  is given by:

$$R(E_0) = \int_{E_0}^0 \frac{dE}{dE/dx} \quad [2]$$

### Introduction

Particle-induced X-ray emission (PIXE) is an elemental analysis technique that employs a beam of energetic heavy charged particles (usually protons of 1–4 MeV) to induce element-specific X-ray emission. Depending on the sample material and thickness and on the conditions of the analysis, the technique offers detection limits at the  $0.1\text{--}10\text{ mg kg}^{-1}$  concentration level for low- $Z$  matrices. Applied in nuclear microprobes, micro-PIXE combines a high sensitivity with the possibility of providing elemental maps with a lateral resolution in the sub-micrometer range.

### Basic Principles

PIXE was introduced in 1970, combining two technical developments into a novel variant of X-ray emission analysis with interesting capabilities. One innovation was the use of lithium-drifted (Si(Li)) detectors, which allow the simultaneous detection of the X-ray intensities of (nearly) all elements in the sample. The other novelty was that X-ray emission was induced by a proton beam of MeV energy instead of by an electron beam or bremsstrahlung radiation from an X-ray tube. The proton beam ejects inner-shell electrons from the atoms in the bombarded specimen (sample), the resulting vacancies are virtually instantaneously filled by outer-shell electrons, and this de-excitation process gives rise to the emission of X-rays whose energies are characteristic for the excited elements. Although the excitation mechanism is analogous to that in the electron microprobe, the much smaller deceleration of the protons (or other ions) in the specimen leads to a much lower bremsstrahlung continuum. The typical PIXE spectrum shown in Figure 1 consists of

characteristic X-ray peaks superimposed on a continuous background. Whereas the former result from the de-excitation of inner-shell vacancies, the background arises from several processes, especially secondary electron bremsstrahlung (SEB).

When a beam of heavy charged particles of a few MeV penetrates into matter, it loses its energy gradually with depth, until it is finally stopped. The energy loss occurs mainly through inelastic Coulomb interactions with bound electrons and in contrast to the case of electron beams, the direction of travel of an ion beam is scarcely altered during the slowing down process. The stopping power  $S(E)$  of an ion with energy  $E$  is defined as the energy loss per unit mass thickness traversed:

$$S(E) = -\frac{1}{\rho} \frac{dE}{dx} \quad [1]$$

where  $\rho$  is the density of the stopping material and  $x$  the distance. As defined here,  $S(E)$  is expressed in  $\text{keV g}^{-1} \text{cm}^2$ . The total path length  $R$  for an ion with incident energy  $E_0$  is given by:

$$R(E_0) = \int_{E_0}^0 \frac{dE}{dE/dx} \quad [2]$$

**Figure 1** PIXE spectrum of an urban aerosol sample recorded using a 'funny filter'. (Reproduced with permission from Campbell *et al.* (1986) *Nuclear Instruments and Methods in Physics Research B* 14: 204–220; © Elsevier.)

**Table 1** Range  $R$  and stopping powers  $S(E)$  for 2.5 MeV protons in several solids

Sample material	Atomic number	Penetration range, $R$ ( $\mu\text{m}$ )	$S(E)$ ( $\text{keV mg}^{-1} \text{cm}^2$ )
C	6	55	122.9
Si	14	68	98.2
Fe	26	27	74.9
Ag	47	28	56.1
Pb	82	37	40.6

As an illustration, for 2.5 MeV protons impinging on various materials, Table 1 lists numerical values for  $S(E)$ , and  $R$ .

### Ionization Processes

The primary purpose of bombarding a specimen with protons or heavier ions in PIXE is to eject bound electrons from the K or L atomic shells. The ejection can also be achieved by means of electrons or photons with energy in the 1–100 keV range. The vacancies will de-excite within  $10^{-16}$  s with the emission of characteristic radiation or Auger electrons or both; the probability of the radiative relaxation is the fluorescence yield  $\omega$ . For low- $Z$  elements ( $Z < 30$ ) and for Kvacancies, the production of Auger electrons is more probable than emission of characteristic radiation; in the case of Lshell vacancies, this is always the case. Nevertheless, for elements with  $Z < 20$ , protons are more efficient than photons or electrons for producing characteristic X-ray. For heavier elements, photon-induced X-ray emission (i.e., X-ray fluorescence, XRF) is more efficient.

### Processes Contributing to the Background

In general, when an electrical charge changes speed or direction, electromagnetic radiation is emitted. The deceleration experienced by the projectiles in PIXE and in electron-induced X-ray emission results in emission of bremsstrahlung photons. In electron-induced X-ray emission, this phenomenon provides the main contribution to the background and has the effect that the limits of detection (LODs) are at the percentage level. Since the bremsstrahlung intensity is inversely proportional to the square of the mass of projectile, the bremsstrahlung background is much smaller with protons than with electrons. As a consequence, other processes prevail over projectile bremsstrahlung in PIXE. Of particular

importance is the SEB; it arises from the electrons that are ejected from the specimen atoms in the slowing down of the protons. The SEB provides a very intense contribution to the background in the PIXE spectrum up to a maximum energy, but it becomes unimportant at higher energies. At high energies, the largest contribution to the background comes from  $\gamma$ -rays. These are produced by nuclear reactions in the specimen; mainly  $(p, \gamma)$ ,  $(p, p'\gamma)$ , and  $(p, \alpha\gamma)$  reactions with light elements ( $Z < 20$ ). The  $\gamma$ -ray background may become quite important when heavier ions (e.g., helium, oxygen) are used as projectiles in PIXE. With protons of a few MeV, the nuclear reaction background prevails over the proton bremsstrahlung in the energy region above 10 keV in the PIXE spectrum. Accordingly, in most PIXE setups, protons are preferred to heavier ions and used at energies between 2 and 3 MeV. Incident energies below 2 MeV are not advisable because of the decrease in ionization cross-sections.

### Instrumentation

Most PIXE work is done with proton beams of 2–3 MeV, which are provided by a small Van de Graaff accelerator. A typical arrangement of a beam line and specimen chamber for conventional broad-beam PIXE (macro-PIXE) is shown in Figure 2. Whereas the beam line is generally assembled from commercially available parts, the specimen chamber usually is not. Consequently, there is a wide variety of configurations. The pressure in the beamline and specimen chamber is typically in the range of  $10^{-6}$ – $10^{-4}$  Pa. High vacuum conditions are not crucial for macro-PIXE, but are very much so in micro-PIXE, where beam defocusing by gas molecules must be avoided.

In macro-PIXE, the proton beam has to be made uniform, defined by collimators (diaphragms), directed onto the specimen and integrated for calibration and monitoring purposes. At the same time, the X-ray and  $\gamma$ -ray background near the X-ray detector must be kept to a minimum. Accordingly, for collimators, specimen holders, Faraday cups, etc., materials with a low  $\gamma$ -ray yield under proton bombardment such as tantalum and graphite are employed. Since fluorine has a high  $\gamma$ -ray yield, the use of fluorine-rich materials such as polytetrafluoroethylene is avoided. On grounds of convenience and cost, the specimen chamber is usually constructed in aluminum, but in order to limit the production of  $\gamma$ -rays, regions of the chamber that are exposed to scattered protons are often lined with graphite foil.

**Figure 2** Schematic overview of a typical PIXE experimental setup. (Reproduced with permission from Malmqvist *et al.* (1982) *Journal of Radioanalytical Chemistry* 74: 125–147; © Elsevier.)

### Beam Handling

In macro-PIXE, one often analyses specimens with a nonuniform distribution of the analyte elements across the size of the beam. For quantitative analysis of such specimens one needs to have a uniform intensity distribution across the beam. The quasi-Gaussian radial intensity distribution of the beam as it emerges from the accelerator can be converted to a rectangular profile in several ways. A first approach is to focus the beam onto a scattering foil (the gold foil in **Figure 2**), which distributes the protons homogeneously over the cross-section selected by the diaphragm. A second method is to create a very narrow beam by means of quadrupole focusing magnets (see below: micro-PIXE) and sweeping this beam rapidly in both  $x$  and  $y$  directions over the specimen area. This does not give a genuinely homogeneous distribution and may therefore produce high instantaneous count rates in the X-ray detector for heterogeneous samples. On the other hand, this method has the advantage of relatively low loss of beam intensity, whereas such losses may be more than 90% in the case of the first method. The third approach consists of defocusing the beam by means of quadrupole magnets and selecting the central, approximately flat-topped portion of the broadened intensity distribution by means of a diaphragm. The beam-defining diaphragm is usually followed by a second one, which does not intersect with the beam, but serves to remove particles that are scattered by the first one.

### X-Ray Detection

For detection of the X-rays in PIXE, one normally uses a Si(Li) detector, although other energy-dispersive detectors (i.e., HPGe detectors) are also occasionally employed, for example, in setups with two X-ray detectors. The preferred location for the X-ray detector is at  $135^\circ$  to the beam direction, because at this angle the intensity of the bremsstrahlung background is significantly less than at  $90^\circ$  to the beam, but in some cases chamber design restrictions result in a  $90^\circ$  orientation.

In contrast to energy-dispersive XRF spectra, PIXE spectra have most of their X-ray intensity in the low-energy region; hence, the spectral shape can be modulated by placing an X-ray absorber between sample and detector. The aim of absorbers is to reduce or eliminate unwanted continuum background and/or intense X-ray peaks and their associated pile-up peaks and at the same time to allow bombardments at higher beam intensities, so that the elements of interest can be measured in shorter bombardment times and with fewer spectral interferences. The absorbers are usually made of organic material (e.g., Mylar) or of light element metal foils (Be and Al). Plain absorbers are employed if complete elimination of the low-energy part of the spectrum is desired. In many cases, however, it is preferable to allow a certain fraction (e.g., a few per cent) of the low-energy X-rays to pass on onto the detector. This can elegantly be realized by resorting to pinhole absorbers (usually called ‘funny filters’ in the PIXE

community). The spectrum of Figure 1 was acquired using a funny filter; elements down to aluminum can be observed.

When measuring minor and trace elements in a high- $Z$  matrix, one can also resort to a critical absorber, which preferentially attenuates the X-rays of the matrix elements. For example, for the analysis of steel a chromium-critical absorber is used. Since the Fe K X-rays lie just above the K edge of chromium, the former will be selectively absorbed, while photons of higher and lower energies will be transmitted.

When one is interested in measuring the light elements ( $Z < 13$ ), only a very thin X-ray absorber may be used, and for the very light elements, a windowless detector or a detector with a very thin polymer window would be advisable. However, the bombardment of a sample with charged particles also gives rise to backscattered particles, and a fraction of these may penetrate into the Si(Li) detector and cause problems. Hence, it is advisable to use an absorber (typically made of Be) that is sufficiently thick to stop all scattered particles, but this hampers or precludes the detection of the light elements. Placing a magnetic deflection trap between the sample and the detector crystal is a viable alternative to an absorber for removing the scattered ions. However, the installation of such a system also results in a lower solid angle of detection.

### Detection of Other Radiation

The bombardment of a specimen with MeV protons does not lead only to the emission of X-rays. Several other interactions, such as elastic and inelastic scattering of the incident particles and the production of prompt  $\gamma$ -rays, also occur. These other interactions form the basis of various other ion beam analysis (IBA) techniques, such as Rutherford backscattering spectrometry (RBS) and particle-induced  $\gamma$ -ray emission (PIGE). These other IBA techniques can often be used in combination with PIXE in order to obtain complementary information (e.g., by extending the elemental coverage down to hydrogen). Consequently, PIXE chambers are usually equipped with appropriate detectors for the complementary IBA techniques. For RBS one normally uses a silicon surface barrier detector, which is placed at a large backward angle ( $\sim 180^\circ$ ) in order to maximize the elemental resolution. For PIGE, one utilizes a Ge or NaI(Tl) detector. Some light elements, such as F and Na, which are difficult (or impossible) to measure by PIXE, have high cross-sections for  $\gamma$ -ray-producing nuclear reactions, so that the combination of PIGE and PIXE allows a more complete elemental analysis.

## Analysis of Thin Specimens

The simplest case of PIXE is that of thin samples. Thin samples do not decrease the energy of the proton beam in an appreciable way during transit and they do not absorb the emitted X-rays on their way to the detector. The 'thinness' criterion is a function of the beam energy and of the sample composition.

### Calibration

When protons of 1–4 MeV are used, elements with  $Z$  up to  $\sim 50$  are generally determined through their K X-rays (typically the  $K\alpha$  line) while the heavier elements are measured through their L X-rays ( $L\alpha$  line). After passage of  $N_p$  protons with incident energy  $E_0$  through a thin specimen, the  $K\alpha$  (or  $L\alpha$ ) line intensity of an analyte element with atomic number  $Z$  and atomic mass  $A_Z$  is given by:

$$Y(Z) = \frac{\sigma_Z(E_0)\omega_Z p_{\alpha,Z}\varepsilon_Z N_A}{A_Z \sin \theta} N_p M_a(Z) \\ = k(Z) N_p M_a(Z) \quad [3]$$

where  $M_a(Z)$ ,  $\sigma_Z(E_0)$ ,  $\omega_Z$ , and  $p_{\alpha,Z}$  apply to the analyte and denote, respectively, the mass per unit area, the ionization cross-section at energy  $E_0$ , the K (or L) fluorescence yield, and the fractional intensity of the  $K\alpha$  (or  $L\alpha$ ) line relative to the total intensity of all the K (or L) lines.  $\varepsilon_Z$  is the absolute detection efficiency (including the solid angle) at the energy of the  $K\alpha$  (or  $L\alpha$ ) line,  $N_A$  is Avogadro's number, and  $\theta$  the angle between the incident proton beam and the specimen surface.  $k(Z)$  is called the thin target sensitivity factor and is expressed in X-ray counts per proton (or unit charge) per  $\mu\text{g cm}^{-2}$ . With regard to the K shell, the compound uncertainty of the fundamental and other parameters that are combined into  $k(Z)$  is of the order of 5–8%. In principle, the use of eqn [3] allows for 'standardless' analysis with an accuracy of better than 10% for elements whose characteristic X-rays are not interfered by others. When L X-rays are used, the potential accuracy is markedly poorer. Instead of relying on fundamental and other parameters (such as the detection efficiency) to obtain the sensitivity factors, most PIXE users prefer to determine the latter experimentally by irradiating uniform standard targets. Generally, these standards are very thin layers ( $M_a = 20\text{--}50 \mu\text{g cm}^{-2}$ ) of elements or compounds evaporated onto Mylar foils or Nuclepore<sup>®</sup> filters. Experimentally determined K and L line sensitivity curves are shown in Figure 3. The accuracy of such a calibration depends almost entirely on the certified areal densities of the standard films; usually they are accurate to within 5%. Once a

**Figure 3** Thin target sensitivity curves obtained with micromatter standards. (Reproduced with permission from Johansson SAE, Campbell JL, and Malmqvist KG (1995) *Particle-Induced X-Ray Emission Analysis. Chemical Analysis Series*, Vol. 133, p. 59. Wiley; © John Wiley & Sons, Inc.)

PIXE system has been calibrated with these external standards, the exercise does not need to be repeated for every analysis. Furthermore, in practice, one does not need to measure  $k(Z)$  for each possible analyte element. A complete sensitivity curve can be obtained by interpolation, thereby making use of the fundamental parameters.

### Limits of Detection

As in other spectrometric techniques, the LODs in PIXE are determined by the sensitivity factors and by the spectral background intensity where the analyte signal (X-ray line) is expected. The LOD values in PIXE are proportional to:

$$\frac{I_B^{1/2}}{I_Z} \left( \frac{\text{FWHM}}{Q\Omega} \right)^{1/2} \quad [4]$$

where  $Q$  is the integrated (preset) proton charge,  $I_Z$  and  $I_B$  are the net intensity of a characteristic peak of element  $Z$  and the integrated background below that peak respectively, FWHM its full-width at half-maximum, and  $\Omega$  is the detector solid angle. Of the factors shown in eqn [4], usually the dose  $Q$  and the peak-to-background ratio ( $I_Z/I_B$ ) can be used to improve

**Figure 4** Contour plot of the limit of detection (LOD) as a function of incident proton energy and atomic number of the analyte for a  $0.1 \text{ mg cm}^{-2}$  thick carbon matrix. Experimental conditions: detector FWHM 165 eV, solid angle of detection 38 msr, collected charge  $10 \mu\text{C}$ . The background interval selected for calculating LOD was equal to one FWHM. (Reproduced with permission from Johansson and Johansson (1976) *Nuclear Instruments and Methods* 137: 473–516; © Elsevier.)

the LOD values, since the other factors are geometry and instrument dependent. The preset charge  $Q$  can be increased by increasing measurement time or beam current. With regard to the  $I_Z/I_B$  ratio, this depends on the incident beam energy and on the specimen matrix and possible support (backing) film. It can be improved by using a very thin backing film and by removing the matrix elements from the sample, thereby preconcentrating the analyte elements. Figure 4 shows the variation with proton energy of the LOD for the case of a  $0.1 \text{ mg cm}^{-2}$  carbon matrix. For this matrix, irradiated over  $10 \text{ mm}^2$ , a LOD of  $1 \text{ mg kg}^{-1}$  ( $10^{-6}$ ) corresponds to an absolute analyte mass of 10 pg. It is assumed in Figure 4 that elements with atomic number up to  $\sim 50$  are determined through their  $K\alpha$  X-ray line and the heavier elements through their  $L\alpha$  line. As can be seen in the figure, there is a valley of optimum detection limits for both the K and L cases, with the best K LODs obtained at lower proton energy than the best L LODs. Furthermore, within either the K or L case, the bombarding energy for optimum detection limits depends upon the atomic number of the analyte elements of interest, with higher bombarding energies favoring the heavier elements. Selection of the energy should thus be made with the objective of the analysis in mind, but in practice some compromise is necessary. Finally, it should be noted that the LODs worsen as the atomic number of the matrix increases.

### Preparation of Thin Specimens

The specimen preparation depends upon the type of sample, its composition, the information looked for

(bulk concentrations or spatially resolved data), the elements of interest, and the mode of irradiation (vacuum or nonvacuum). For nuclear microprobe analyses, special requirements apply. For certain samples, the preparation of thin specimens is impossible or even not allowed, e.g., when the sample has to be returned unaltered after the analysis. In the analysis of atmospheric aerosols, a very successful application area of PIXE, the air can simply be drawn through a thin filter that can then be analyzed without further treatment. Biomedical samples are often freeze-dried and powdered. Thin (or semithick) specimens are then prepared by depositing a few milligrams of the powdered material onto a thin backing film and fixing it with a trace-element-free 'glue' (e.g., polystyrene in xylene). The freeze-drying removes the water of the material and can be considered as a preconcentration step, which will lead to improvement in LODs. Greater preconcentration may be obtained by acid digestion (wet ashing) or by dry ashing, so that LODs are even further improved. For dry ashed material, thin specimens may be prepared in the same way as for the powdered freeze-dried material. Acid-digested samples can be pipetted onto a thin backing film and dried. This may also be done with other liquid samples, such as body fluids and environmental surface water samples.

### Precision and Accuracy

The reproducibility (precision) of an entire PIXE analytical procedure (including the contribution from sample processing and specimen preparation) can be examined by preparing several specimens from the same material, subjecting these to PIXE, and calculating a standard deviation from the spread in the results obtained. In the analysis of biological, geological, and atmospheric aerosol samples, a relative standard deviation of 1–2% is often the ultimate practical limit of precision. The accuracy of a PIXE procedure may be evaluated by analyzing (certified) reference materials or through comparison with other analytical techniques. The literature contains many examples of such studies. As an example, for biological materials a total of 18 elements were measured in up to 14 (certified) reference materials; from a comparison of the PIXE results with the reference values it was concluded that the overall accuracy was better than 5%.

### Analysis of Specimens of Intermediate and Infinite Thickness

In many cases, the specimens do not fulfill the 'thinness' criterion, and one has to consider the proton

energy loss within the specimen and the attenuation of the emerging characteristic X-rays. Such specimens are said to be of 'intermediate thickness' or 'infinitely thick' (when they are thicker than the particle range). For both types of specimens, eqn [3] has to be replaced by

$$Y(Z) = \frac{\omega_Z p_{a,Z} \varepsilon_Z N_A}{A_Z} N_P C_Z \int_{E_0}^{E_f} \frac{\sigma_Z(E) T_Z(E)}{S(E)} dE \quad [5]$$

where  $C_Z$  is the concentration of the analyte and  $E_0$  and  $E_f$  are the incident proton energy and the energy of the protons after passage through the target respectively ( $E_f = 0$  for an infinitely thick specimen).  $E$  is the proton energy,  $T_Z(E)$  the transmission of the X-rays of the analyte from successive depths in the specimen, and  $S(E)$  the matrix stopping power.  $T_Z(E)$  is itself given by

$$T_Z(E) = \exp\left(\frac{-(\mu/\rho) \sin \theta}{\sin \phi} \int_{E_0}^{E_f} \frac{dE}{S(E)}\right) \quad [6]$$

with  $(\mu/\rho)$  the mass attenuation coefficient for the analyte X-rays in the sample matrix, and  $\phi$  the angle between the specimen surface and the specimen-detector axis (i.e., the X-ray take-off angle). When specimens of intermediate thickness are analyzed, the transmitted proton energy  $E_f$  (or rather the energy loss  $E_0 - E_f$ ) is needed for evaluating the integral in eqn [5]. This implies knowledge (or determination) of the specimen mass thickness, because the energy loss is related to the latter through the matrix stopping power. Alternatively, the energy loss can be measured experimentally. As for thin specimens, several approaches for quantitative analysis are possible for specimens of intermediate or infinite thickness. One can make use of experimentally determined thin-target sensitivity factors  $k(Z)$ , as defined by eqn [3], so that eqn [5] can be written as:

$$Y(Z) = \frac{k(Z)}{\sigma_Z(E_0)/\sin \theta} N_P C_Z \int_{E_0}^{E_f} \frac{\sigma_Z(E) T_Z(E)}{S(E)} dE \quad [7]$$

In the analysis of infinitely thick specimens, one can also utilize experimental thick-target sensitivity factors instead of relying on the fundamental parameter approach or on experimental thin-target sensitivities. The thick-target sensitivity factors incorporate the integral of eqn [5] and are usually expressed in X-ray counts per  $\mu\text{C}$  and per  $\mu\text{g per g}$ . They are commonly derived from PIXE measurements on standard samples. In a strict sense, the thick-target factors are only valid for the analysis of unknown samples with identical (matrix) composition as the standards, but in practice, some variability in composition can be tolerated or corrected for.

The necessary correction factor is in this case the ratio of the integral of eqn [5] for the standard to the corresponding integral for the unknown.

The LODs for samples of intermediate or infinite thickness are determined by the same factors as in the case of thin specimens. However, whereas thin specimens often consist of a light-element matrix, the matrix of thick specimens is often made up of higher-Z elements, as is the case with geological and metallurgical samples. Consequently, intense X-ray peaks and their associated tails and pile-up peaks show up in the PIXE spectrum, and the heavier matrix also leads to an increased bremsstrahlung background. As a consequence, LOD values are in the  $1\text{--}10\text{ mg kg}^{-1}$  range for thick geological and metallurgical samples, versus  $0.1\text{--}1\text{ mg kg}^{-1}$  for thin (and thick) samples with a light element matrix.

## Nonvacuum PIXE

Proton bombardment in vacuum gives rise to heating of the specimen and this may damage sensitive objects (such as ancient documents) or lead to losses of volatile elements for biomedical samples. These problems can largely be avoided by resorting to atmospheric pressure or moderate vacuum instead of high vacuum during analysis. Because the accelerator requires a high vacuum, the ion beam must be extracted into the moderate vacuum or atmospheric pressure region through a thin exit foil. The beam eventually deteriorates this foil, and therefore its material has to be carefully selected. The best choice is polyimide foil (Kapton), which withstands high intensities and a high radiation dose before mechanical breakdown. The chamber gas is normally helium or nitrogen. The choice of chamber atmosphere is determined by the objectives of the analysis and by the samples to be analyzed. A rather low pressure of helium gas, for example, suffices to improve heat conductivity and to reduce thermal losses of elements or compounds. On the other hand, an external beam in air is needed when large objects are to be analyzed without sectioning or subsampling. This is very important in archaeology and art science, for example. The disadvantages of bombardment in air are that there is a danger of sample oxidation during irradiation and that interfering argon X-ray lines are present in the spectrum. The strong argon lines may also be used to monitor the beam fluence, however, which is otherwise difficult to do in nonvacuum PIXE.

When using external beams, some safety precautions are necessary. Besides the obvious hazard of direct exposure, there is the potential exposure to the

scattered beam and the activation of the air to form positron-emitting radionuclides.

In external beam or nonvacuum PIXE (in air or in a helium or nitrogen atmosphere), poorer detection limits are expected because of the background contribution from interactions in the beam exit foil material and in the air or chamber gas and, for the light elements, also because of the substantial attenuation of their soft X-rays by the same gases. However, practical detection limits in nonvacuum PIXE appear to be comparable to those in vacuum PIXE, at least for analyte elements with atomic number above 25.

## Micro-PIXE

In nuclear microprobe or micro-PIXE analysis, the particle beam is collimated and/or focused down to dimensions in the range of  $1\text{--}50\text{ }\mu\text{m}$ . The best systems currently available are able to produce a spatial resolution of  $\sim 0.5\text{ }\mu\text{m}$  at the specimen while maintaining an ion current that is useful for PIXE analysis ( $>100\text{ pA}$ ). **Figure 5** shows the layout of a nuclear microprobe. Although the exciting particles form the only difference between micro-PIXE and energy-dispersive electron probe microanalysis, equipped with an X-ray detection system, much better peak-to-background ratios and, consequently, lower detection limits are obtainable by micro-PIXE. As shown in **Figure 5**, the normal components of a nuclear microprobe comprise a particle accelerator (normally electrostatic) with a very bright ion source, precision collimators, magnetic or electrostatic quadrupoles for focusing, and a scanning system to raster the beam over the sample, as in a scanning electron microscope. The detection system is, in principle, identical to that for macro-PIXE but usually includes complementary surface barrier detectors for scattered particles and for particles emitted in nuclear reactions to extend the analytical arsenal. Sometimes a detection system for secondary electrons and/or a detection system for near-visible light, iono-luminescence, are also included for imaging of the specimen. The data are acquired in dedicated computer systems that can produce both quantitative results and qualitative elemental maps.

As is the case for macro-PIXE, micro-PIXE may also be carried out under nonvacuum conditions. Because of scattering of the beam by the gas, however, nonvacuum micro-PIXE is only feasible for moderately small beam sizes ( $20\text{--}100\text{ }\mu\text{m}$ ). After collimation and/or focusing, the beam is passed to the nonvacuum region through a pinhole or an exit foil. If the spatial resolution requirements are not too

**Figure 5** Components (not to scale) of a typical nuclear microprobe system: (A) electrostatic particle accelerator; (B) primary object aperture; (C) secondary collimator; (D) focusing system; (E) scanning system; (F) video camera and microscope; (G) surface barrier detector for scattered particles; (H) X-ray detector; (I) specimen; (J) surface barrier detector for transmitted particles (STIM); (K) front-end CAMAC with data bus; (L) main computer and display with elemental map. high, the nonvacuum micro-PIXE technique is rather straightforward and simple to use. It is very useful when examining large samples or sensitive art objects, such as bronze figures and ancient documents.

Micro-PIXE is related to micro-XRF and especially to synchrotron induced micro-XRF. There are a lot more micro-PIXE installations available than SR micro-XRF.

## Applications

Many of the early applications of PIXE took advantage of its capability to analyze very small specimens (e.g., of mass 0.1–1 mg). The technique found use in many disciplines, such as biology, medicine, environmental and earth sciences, arts and archaeology, and material sciences, achieving detection limits below  $1 \text{ mg kg}^{-1}$  in favorable specimen

types. The samples that can be handled are very diverse. However, considering that the bombardment is normally done in a vacuum, it is evident that the technique is more suitable for analyzing solids than liquids. PIXE analysis of liquids normally involves some preconcentration by drying or some other physical or chemical separation of the analytes from the liquid phase. As far as the analysis of solids is concerned, there are numerous analytical problems for which PIXE is a highly suitable technique. Examples are the multielemental analysis of milligram-sized samples consisting of a light-element matrix (e.g., biomedical and atmospheric aerosol samples), the nondestructive analysis of millimeter-sized areas on a large sample or of thin superficial layers on a bulk sample, and various problems that require sensitive analysis with high spatial resolution.

## Biological and Medical Samples

Most samples of biological origin are composed of essentially organic material, so that its matrix elements are light and do not give rise to characteristic X-ray lines in the spectrum. Furthermore, the electron bremsstrahlung background is lower for an organic matrix than for a matrix of heavy elements. Biomedical samples are therefore well suited for trace element determinations by PIXE. The elements of interest in biological materials are either 'essential' minor or trace elements (e.g., K, Ca, Mn, Fe, Cu, Zn, and Se) or 'toxic' trace elements (e.g., Cd and Pb), and many of these, with some exceptions, such as Cd, can suitably be determined by PIXE in most tissue types. Consequently, ever since the development of PIXE started, biological and medical applications have been prominent areas of application. However, in the last decade, new ultratrace techniques such as inductively coupled plasma-mass spectrometry emerged and the emphasis has shifted from 'total' element determinations toward elemental speciation, for which PIXE is less suitable. In applying PIXE to biomedical problems one should therefore look for cases where one can fully utilize the special advantages of PIXE, such as high spatial resolution, accurate quantitative analysis, and small samples. Particularly micro-PIXE, as used in the nuclear microprobe, is invaluable in biomedical trace element research. It is being applied to single cells and soft and hard tissues of human or animal origin and to samples from the plant sciences field. The relatively high, but still limited, lateral resolution of the nuclear microprobe makes it ideal for studying plant material. The cells are often rather large and it is possible to examine subcellular structures even with the modest beam resolution.

Several reviews (see Further reading section) give examples of micro-PIXE in the plant sciences. One example is a study of plant resistance to pathogen infection. A resistant genotype of a wild plant (*Lagenaria sphaerica* (Sonder) Naudin, Syn. *Lagenaria mascarena* Naudin) belonging to the Cucurbitaceae was inoculated with a foliar fungal pathogen (*Sphaerotheca fuliginea* (Schlecht. ex Fries) Poll. An accumulation of Ni, Cu, Zn, Mn, Fe, Ca, Ti, As, and Sr as well as a drastic depletion of macronutrients (P, S, Cl, K) occurred in the invaded region during the first four days. Six days after inoculation, necrotic cells with high levels of Mn (Figure 6) surrounded the lesions. Si deposition in concentrations of up to 23 wt.% occurred after accumulation of most metals in the fully necrotic lesions. Changes of elemental distribution with time suggest that metal accumulation to phytotoxic levels may contribute to death of infected cells, and that subsequent Si accumulation provides an impermeable, nontoxic barrier protecting the surrounding uninfected tissue.

### Atmospheric Aerosols

The multielement analysis of airborne particulate material (atmospheric aerosols) has been a very popular and highly successful application of PIXE since the early days of the technique. Considering that atmospheric aerosols are often collected as a thin sample layer on some thin filter or substrate film, that

such samples can be analyzed nondestructively by PIXE without sample preparation, that the sample matrix consists of light elements, and that a 5–10 min bombardment suffices to detect up to 20 elements, including interesting anthropogenic elements, such as S, V, Ni, Cu, Zn, As, and Pb, the analysis of aerosol samples forms almost an ideal application of PIXE. Compared to energy-dispersive XRF, PIXE requires much less sample mass, so that it allows the use of compact samplers with high time and size resolution. Another advantage of PIXE is that it can be complemented with other IBA techniques, so that the light elements (H, C, N, and O) that make up most of the aerosol mass can be measured as well. Motivation for the study of atmospheric aerosols and of their physical and chemical characteristics is that they reduce visibility, lead to radiative forcing on climate, affect human health, contribute to acidification of terrestrial and aquatic ecosystems, and cause damage to structures and buildings.

There is a wealth of examples on the application of PIXE to atmospheric aerosol samples. The aerosol samples analyzed by PIXE range from those collected indoors (e.g., in work environments) or near specific pollution sources to samples dealing with urban, regional, and global air pollution problems, and those collected in areas as remote as the Arctic and Antarctic. As an example, results are presented in Figure 7 from a study that was conducted in the Kruger National Park, South Africa, within the framework of the Southern African Regional Science Initiative (SAFARI 2000). Size-fractionated samples were collected with a 12-stage small deposit area low pressure impactor (SDI), which was developed for subsequent analysis by PIXE, and analyzed for 28 elements. The average mass size distributions for eight selected elements are shown in Figure 7. They

**Figure 6** Quantitative maps of Ca, K, Mn, and Ni in a 6-day lesion caused by *Sphaerotheca fuliginea* on resistant *Lagenaria sphaerica* (Cucurbitaceae) leaf. **Figure 7** Average mass size distributions for eight elements, as obtained from PIXE of 64 SDI samples collected during SAFARI 2000. (Reproduced with permission from Maenhaut W *et al.* (2002) *Nuclear Instruments and Methods in Physics Research B* 189: 254–258; © Elsevier.)

have a bimodal or trimodal size distribution, most of their mass (with the exception of As) is in the sub-micrometer size range, and the major fine mode peaks at  $\sim 0.3 \mu\text{m}$  aerodynamic diameter. The fine modes point to high-temperature sources and/or gas-to-particle conversion processes for the eight elements. The likely sources are biomass burning, fossil fuel (coal) combustion, and/or industrial activities. Other elements (i.e., Al, Si, Ca, Ti, Mn, Fe, Sr) had essentially a unimodal coarse size distribution, and over 90% of their mass occurred in super-micrometer-sized particles; these elements result mainly from dispersion of soil dust.

### Earth Science Applications

In the earth sciences, as well as in related economic activities (e.g., mining, prospecting), there is a significant need for elemental analysis. Because of its unique ability to provide quantitative trace element information on a micrometer scale, micro-PIXE offers great potential for mineral prospecting and for improving our understanding of basic geological processes. The nuclear microprobe could serve as an excellent complement to the electron microprobe in these areas.

The penetrating, nondestructive nature of MeV proton beams makes the nuclear microprobe ideally suited to *in situ* analysis of individual fluid inclusions in minerals. Fluid inclusions are small samples of fluid trapped in a host mineral during growth or later during healing of fluid filled fractures. They provide samples of the broad spectrum of fluids that have interacted with the earth's crust and upper mantle over geological time. **Figure 8** shows PIXE images of a carbonate-rich melt inclusion in clinopyroxene. The images show spinifex needles of olivine and a large cubic phlogopite (high Rb), set in a matrix of

elongated calcite crystals (high Sr). Nb shows evidence for concentration into rare minor phases (e.g., marked by the arrow in the figure).

### Applications in Art and Archaeology

One application of PIXE and in particular of micro-PIXE that has been unexpectedly successful is the analysis of archaeological and art objects. The aims of such analysis are to provide answers about provenance, authenticity, deterioration, and conservation of the objects. Recognition of the potential of PIXE and other IBA techniques for art investigations has led to the installation of an IBA facility in the scientific laboratory of the Louvre museum in Paris, with a subsequent inclusion of a nuclear microprobe. Similar facilities are now used in several other laboratories specializing in archaeology. Since nondestructiveness is more important here than in other applications, there must often be a trade-off between beam size and intensity in order to avoid damaging the object studied. Larger probe sizes and lower intensities than in other fields of application are normally used. External beam microprobes are particularly useful. Applications of the nuclear microprobe in art and archaeology range from the analysis of antique bronzes and Iron Age tin artifact metals, over gold jewellery, pigments, and paintings, to the inks used in the Gutenberg bible, 'Vinland' map, documents of Galileo, and papyrus from the 'Book of Death' of ancient Egypt.

Besides micro-PIXE, macro-PIXE has also been extensively used in art and archaeology, and found to provide very useful information. Actually, the distinction between micro- and macro-PIXE is difficult to make in this field of application, as a lot of work is carried out with (external) probes with beam

**Figure 8** Dynamic analysis PIXE images of a carbonate-rich melt inclusion in clinopyroxene (in a  $200 \mu\text{m}$  thick polished section). (Reproduced with permission from Ryan *et al.* (2001) *Nuclear Instruments and Methods in Physics Research B* 181: 578–585; © Elsevier.)

sizes ranging from a few tens of a micrometer to  $\sim 1$  mm. Also, one often applies both micro- and macro-PIXE analyses on the same samples. The multielement character of PIXE and the speed of analysis are useful in provenance studies of pottery and earthenware. Obsidians and prehistoric flint tools have been examined by PIXE and other IBA techniques with the aim to trace ancient trade routes or to determine for which purpose the tools were used. Cast iron, ancient iron slag, archaeological bronzes, ancient Greek copper coins, precious metals, and gold artifacts have also been the subject of studies with macro-PIXE and other IBA techniques.

### Introduction

It has only been since the 1970s that synchrotron radiation (SR) has been employed on a routine basis as a radiation source for X-rays. SR is emitted when charged particles are accelerated by means of a magnetic field perpendicular to their direction of motion. At the heart of a synchrotron light source is an electron (or positron) storage ring, i.e., an evacuated tube through which a densely packed beam of electrons circulates. SR radiation was discovered as a spurious radiation in high-energy particle accelerators (first-generation SR sources), then developed specifically for generating X-rays (second-generation sources). Significant in up-to-date SRs of the present third generation is the systematic use of insertion devices that are placed in the straight sections of the storage ring (wigglers and undulators). Wigglers consist of magnetic structures that create multiple oscillations around the beam path and thus increase both the energy and intensity of the radiation. Undulators are designed to create smaller and more frequent deflections, giving rise to interference effects and in such conditions the coherent radiation is concentrated around specific energies. In addition,

X-ray optics of increased sophistication is used to amplify considerably both flux and brilliance.

A considerable number of storage rings exploit microscopic analysis with microscopic X-ray fluorescence analysis (SR  $\mu$ -XRF) combining the advantages of XRF as an elemental analytical tool with the unique possibilities of the SR. Simultaneously, other analytical uses of intense X-ray beams are being developed. Of special importance are the third-generation storage rings at the European Synchrotron Radiation Facility (ESRF), Grenoble, France, the Advanced Photon Source (APS), Argonne, USA, and SPring-8, Harima, Japan. Compared to earlier second-generation rings and to other recently constructed SR facilities they are characterized by their high energy of 6–8 GeV. Other new SR installations also incorporate insertion devices in smaller, less energetic storage rings.

### Properties of Synchrotron Radiation

Synchrotron X-ray beams have unique properties that make them desirable for use in many disciplines that require intense X-ray beams. First, they have a continuous energy distribution. Via suitable monochromating devices, monoenergetic beams can be produced over a wide energy range. In the horizontal direction, X-rays are emitted in a continuous band, whereas in the vertical plane they are efficiently collimated, making it possible to produce intense

sizes ranging from a few tens of a micrometer to  $\sim 1$  mm. Also, one often applies both micro- and macro-PIXE analyses on the same samples. The multielement character of PIXE and the speed of analysis are useful in provenance studies of pottery and earthenware. Obsidians and prehistoric flint tools have been examined by PIXE and other IBA techniques with the aim to trace ancient trade routes or to determine for which purpose the tools were used. Cast iron, ancient iron slag, archaeological bronzes, ancient Greek copper coins, precious metals, and gold artifacts have also been the subject of studies with macro-PIXE and other IBA techniques.

### Introduction

It has only been since the 1970s that synchrotron radiation (SR) has been employed on a routine basis as a radiation source for X-rays. SR is emitted when charged particles are accelerated by means of a magnetic field perpendicular to their direction of motion. At the heart of a synchrotron light source is an electron (or positron) storage ring, i.e., an evacuated tube through which a densely packed beam of electrons circulates. SR radiation was discovered as a spurious radiation in high-energy particle accelerators (first-generation SR sources), then developed specifically for generating X-rays (second-generation sources). Significant in up-to-date SRs of the present third generation is the systematic use of insertion devices that are placed in the straight sections of the storage ring (wigglers and undulators). Wigglers consist of magnetic structures that create multiple oscillations around the beam path and thus increase both the energy and intensity of the radiation. Undulators are designed to create smaller and more frequent deflections, giving rise to interference effects and in such conditions the coherent radiation is concentrated around specific energies. In addition,

X-ray optics of increased sophistication is used to amplify considerably both flux and brilliance.

A considerable number of storage rings exploit microscopic analysis with microscopic X-ray fluorescence analysis (SR  $\mu$ -XRF) combining the advantages of XRF as an elemental analytical tool with the unique possibilities of the SR. Simultaneously, other analytical uses of intense X-ray beams are being developed. Of special importance are the third-generation storage rings at the European Synchrotron Radiation Facility (ESRF), Grenoble, France, the Advanced Photon Source (APS), Argonne, USA, and SPring-8, Harima, Japan. Compared to earlier second-generation rings and to other recently constructed SR facilities they are characterized by their high energy of 6–8 GeV. Other new SR installations also incorporate insertion devices in smaller, less energetic storage rings.

### Properties of Synchrotron Radiation

Synchrotron X-ray beams have unique properties that make them desirable for use in many disciplines that require intense X-ray beams. First, they have a continuous energy distribution. Via suitable monochromating devices, monoenergetic beams can be produced over a wide energy range. In the horizontal direction, X-rays are emitted in a continuous band, whereas in the vertical plane they are efficiently collimated, making it possible to produce intense

X-ray beams with little angular divergence. As the electrons circulate in equally spaced packets ('bunches') around the ring, a synchrotron is a pulsed X-ray source, with a width of typically 1 ns and, e.g., a 20 ns period. This feature makes synchrotron light very interesting for performing time-resolved studies. In addition, third-generation SR sources provide coherent radiation. The best known feature of synchrotron sources, however, is their high intensity, which may be more than a factor  $10^{12}$  higher than the output of conventional X-ray tubes (see Figure 1).

A particular advantage of SR  $\mu$ -XRF is the extremely high source brilliance (number of photons emitted per unit source area in a unit angle of emission and energy,  $\text{photons s}^{-1} \text{ mrad}^{-2} \text{ mm}^{-2}$  per 0.1% of radiation bandwidth). The high intensity and directionality implies that SR is ideally suited for generating microfocused X-ray beams with very high intensity, now well exceeding  $10^{10}$  photons  $\text{s}^{-1} \mu\text{m}^{-2}$  in a spot size that is presently down to  $\sim 100$  nm.

In addition, in the plane of the storage ring the radiation is linearly polarized with the E-vector parallel and the B-vector normal to the storage ring plane. The radiation is highly collimated along the direction tangential to the movement of the electrons in the ring thus facilitating the delivery of the radiation to a predefined sample area. The polarization of the incident radiation can be used to reduce the

relative contribution of scattered radiation reaching the detector, as scattering cross-sections are dependent on the polarization whereas the photo-absorption cross-sections are not. When performing measurements in the plane of the SR source this increases the signal-to-background ratios by several orders of magnitude (directly dependent on the degree of polarization achieved).

Thanks to the high directionality of the beam, quasi-monochromatic X-ray microbeams can be generated from the white SR spectrum through the use of X-ray monochromators. By tuning the energy over a given energy range, the strong energy dependence of the inner-shell photoelectric cross-sections can be exploited to either increase the specificity of measurements or, else, to obtain speciation information in the XAS application mode (see further).

## Focusing of X-Rays

Limiting the flux throughput through pinholes is insufficient for most practical analytical purposes; hence, techniques for generating intense X-ray microbeams are based on the use of various types of X-ray optics. Refractive lenses that are extensively used in visible or ultraviolet light optics are more difficult to use for X-rays because the refractive index,  $n$ , is very close to and slightly smaller than 1.000 by a factor  $\delta$ . The refractive index can be expressed as

$$n = 1 - \delta \quad \text{with } \delta = \alpha + i\beta \quad [1]$$

where  $\alpha$  is the absorption index and  $\beta$  the refractive index decrement.  $\delta$  is typically between  $10^{-5}$  and  $10^{-7}$ . In these conditions, the focal distance  $f$  of a single-element refractive lens (a small spherical void in a low  $Z$  material in, e.g., Al) for a parallel beam is very long (of the order of several tens of meters for a  $300 \mu\text{m}$  hole) and given by

$$f = R/2\delta \quad [2]$$

Linear arrays of  $N$  single-element lenses, however, provide reasonable focal distances (of 1–2 m) for parallel SR X-ray beams:

$$f = R/2N\delta \quad [3]$$

Such lenses are cheaply constructed but suffer from the absorption and scattering. Many other techniques for the formation of intense X-ray microbeams are available on the basis of the use of various types of X-ray optics based on refraction, diffraction, or reflection: bent mirrors, crystals and multi-layers, linear and tapered glass mono-capillaries, complex polycapillary lens systems, transmission Fresnel zone

**Figure 1** X-ray source improvements as a function of time, characterized by the source brilliance.

plates, Bragg–Fresnel lenses, one- or two-dimensional (1D, 2D) wave guides. Flux throughput through pinholes for limiting the beam is insufficient for most analytical applications.

In a number of  $\mu$ -XRF installations, capillary optics are used as focusing devices because of their inherent constructional simplicity and the fact that they provide a good lateral resolution and can be used for both polychromatic and monochromatic X-rays. The working distance between capillary tip and sample is short, typically  $<100\mu\text{m}$ . Another popular design is based on Kirkpatrick–Baez focusing mirrors that simultaneously provide a monochromatic and focused beam. Such systems are achromatic (the spot position is independent of the incident energy) and provide a long working distance. They are quite popular for X-ray absorption spectrometry applications (see further), as the beam position remains fixed while scanning over a specific edge.

## Synchrotron X-Ray Microanalysis

SR  $\mu$ -XRF offers a number of advantages compared to other microprobe techniques: it combines high spatial resolution with high sensitivity, can be used in atmospheric conditions, and is relatively insensitive to beam damage to the sample. As we will show further in this section, the simplicity of the method and the quite good understanding of the physics of the processes involved make it more adaptable for quantitative analysis than a number of other beam methods of analysis. The method is now well accepted as an important tool for microscopic elemental analysis, complementing other beam methods of analysis that rely on electron, ion, photon, or laser beams.

The polarization of the incident radiation can be used to reduce the relative contribution of scattered radiation reaching the detector. This increases considerably the signal-to-background ratios and subsequently detection limits. In addition, highly monochromatic X-ray microbeams can be generated through the use of X-ray monochromators. Monochromatic radiation is normally obtained with a double crystal monochromator consisting of a pair of suitable crystals, e.g., in silicon at a particular crystallographic orientation. The energy selection is based on Bragg's law. By tuning the energy of the beam, the strong energy dependence of the inner shell photoelectric cross-sections can then be exploited to increase specificity of measurements, to obtain chemical-state information on elements of interest (speciation) and to make quantification of the detected X-ray intensities easier. Contrary to the

vacuum requirements of most other microprobe methods, samples are normally observed in the ambient environment allowing the measurement of samples in their natural (e.g., in wet) conditions.

The energy resolution of the double crystal monochromator is of the order of  $\Delta E/E = 10^{-4}$  or less, and this is sufficient for absorption edge applications. A direct exploitation mode with broadband polychromatic excitation is also possible. It has the advantage that (nearly) all elements in the sample are excited with quite comparable efficiency providing a more uniform spectrometer response over the range of elements of interest. Since losses in flux due to the monochromator do not occur, the elemental efficiency of polychromatic set-ups is also higher than when monochromatic excitation is used, making it more appropriate for general-purpose materials characterization. In such circumstances, however, quantification of the detected X-ray intensities is more complicated. Also, the signal-to-noise ratios, and hence, detection limits, do not match those obtained with monochromatic excitation. For quantitative analysis the use of monochromatic radiation is, in general, a preferable approach.

In its primary utilization mode as a tool for elemental analysis by XRF analysis a high photon flux rather than such a high-energy resolution is required and an energy resolution of the order of  $\Delta E/E = 10^{-2}$  is sufficient for the purpose. Synthetic multilayers, made by vacuum deposition of alternate thin layers of two materials with different electron densities provide this resolution. On the other hand, through a wide energy band-pass, they yield a photon flux one to two orders of magnitude higher than available with a high-resolution double crystal monochromator.

Excluding the inherent complexity of the SR X-ray source problems involved with monochromatization and focusing of the X-rays, instrumentation for X-ray microanalysis is conceptually simple and consists of a mechanical sample stage with high-precision computer controlled microstepping motors for X, Y, Z sample movement, a semiconductor-type detector for measurement of the fluorescent radiation, visualization tools for observation of the sample, and a range of diagnostic and control tools. One typical configuration is shown in **Figure 2**.

In typical setups available relative detection limits (DL) are  $<0.1\mu\text{g per g}$  for elements of  $Z > 25$  but DLs down to a few ppb are possible for quite a number of elements. Absolute DLs are  $<1\text{ fg}$  for elements on the basis of a flux in the focused beam of  $10^9$ – $10^{10}$  photons  $\text{s}^{-1}$ . For the measurement of elemental distribution maps, spectra are taken as the sample is moved over the beam path. Two-dimensional mapping of the

repartition of elements in larger objects than the X-ray beam is possible with relative detection limits in the ppb region and absolute detection limits for many elements well below the femtogram level.

## Synchrotron Computerized X-Ray Fluorescence Microtomography

As a result of the large penetration and the considerable sampling depth of the X-ray beam, the conventional XY-type of scanning a sample through the microbeam yields 2D images that are actually projections of the 3D compositional structure. This particular drawback can be turned into an advantage by the use of computed X-ray fluorescence microtomography (XFCT), an emerging technique capable of providing 3D, potentially quantitative information on the elemental distributions in the probed sample volume with trace-level detection limits. In XFCT, the sample is irradiated under various observational angles, thus creating different 2D projections of the same 3D structure. The sample is mounted on a goniometer head fixed to a rotation stage. Instead of an XY scan the sample height is kept fixed and an  $X\theta$  scan is performed varying  $\theta$  systematically by small increments (e.g., in steps of  $3^\circ$ ) to obtain the so-called 'sinograms' of the different elements. Through the use of appropriate reconstruction algorithms these can be reconstructed into XZ maps. The procedure can then be related to obtain 3D images of medium-to-heavy elements inside the samples (see Figure 3).

The entire reconstruction in 3D of an object is quite time consuming at present. Techniques are being developed, however, to speed up the measurement process, combining fast detector systems, high-speed data networks, and parallel computing systems.

## X-Ray Absorption Methods

In the applications of X-ray absorption spectrometry (XAS, also called X-ray absorption fine structure spectroscopy, XAFS) the energy dependence of the inner shell photoelectric cross is exploited to increase specificity of measurements or to obtain information on the chemical environment (speciation analysis).

Extended X-ray absorption fine structure analysis provides information on the number, the atomic number, and the distance of neighboring atoms. The method is based on irradiation with a highly monochromatic X-ray beam of tunable energy at ca.  $\Delta E/E = 10^{-4}$  while scanning over a specific absorption edge of an element of interest while recording either the absorption of the beam (absorption XAS), the fluorescence radiation produced (fluorescence XAS), or another shell dependent phenomenon. X-ray absorption near edge structure spectrometry (XANES) measures the position of the edge and characterization can be achieved by exploiting specific features of the X-ray absorption spectrum (coordination number, distances to nearest neighbor atoms). Recently, the combination of  $\mu$ -XRF with spatially resolved XAS became an important tool for speciation in environmental and geological materials and for the study of processes in chemical species transformation. Most  $\mu$ -XAS applications are performed in the XANES fluorescence detection mode serving as a 'fingerprinting' technique on the basis of reference compounds.

## X-Ray Diffraction

X-ray diffraction (XRD) provides the structure of materials. The use of monochromatic excitation combining  $\mu$ -XRF with microscopic XRD ( $\mu$ -XRD) complements localized compositional information with structural information. Mostly, Laue spectra

**Figure 2** Schematic layout of the insertion device 18F instrument at the ESRF; from left to right beam focusing, monitoring equipment for the beam intensity, sample and second beam monitor, different visualization tools.

**Figure 3** (A) Schematic drawing of an X-ray fluorescence microtomography set-up that (B) allows the collection of elemental distributions from a single horizontal slice of the sample. Further slices are obtained by translation.

are taken using a CCD X-ray detector.  $\mu$ -XRD has the distinct information that structural information on a material can be obtained from crystals down to a few (tens) of micrometers in diameter allowing mapping of the local structure/stress of a material.

## Imaging

Several hard X-ray imaging techniques greatly benefit from the coherence of the beams delivered by the modern SR sources. When a coherent beam of X-rays travels through an object both the amplitude and the phase of the wave are modified. Phase imaging is directly related to the small angular size of the source as seen from one point of the sample. Phase radiography and tomography are instrumentally very simple. They are often used in the 'edge detection' regime, where the jumps of density are clearly observed. Recently, a more quantitative approach has been developed, which provides a 3D density mapping of the sample ('holo-tomography'). The combination of diffraction topography and phase-contrast imaging constitutes a powerful tool that can help in monitoring the areas of a sample to be selected for further chemical or structural analysis.

## Applications

It should be clear that with the limited availability of SR sources at the present, the techniques described cannot be applied on a routine basis. One area of applications in analytical chemistry is the use of SR  $\mu$ -XRF as a validation tool for other beam methods for microscopic analysis and assist in providing

reference samples. Microscopic X-ray diffraction ( $\mu$ -XRD) and  $\mu$ -XAS can be applied simultaneously with  $\mu$ -XRF and XFCT to obtain simultaneously as well nondestructive materials characterization providing chemical information and data on crystal-line structure of the sample under investigation as the trace elemental composition and distribution, all this on the microscopic level. The use of the methods described is reserved for solving important problems in environmental sciences, geo-, and cosmochemistry in applications where other microscopic methods fail to provide the necessary sensitivity and specificity.

## Introduction

Zone refining is a method for the ultimate purification of substances – element, inorganic compound, or organic compound. It denotes a family of methods for controlling the distribution of soluble impurities or solutes in crystalline materials. A short molten zone travels slowly through a relatively long solid charge and while traveling redistributes the solute in the charge. This article gives a brief account of the principles and application of zone refining.

Impurities, even at trace levels, may exert a profound influence upon certain properties of metals and compounds. For instance, the presence of even a few foreign atoms in a metal may affect its deformation and fracture properties, electrical conductivity, or corrosion resistance. This necessitates a study of matter in a high state of purity, which may be achieved following a large number of fractionations or chemical separations using high-purity reagents and guarding against contamination from vessels, laboratory, and even personnel. Handling samples at various stages introduces impurities and this limits the production of high-purity materials. In zone refining, this problem is solved by melting only a small part of the material and slowly passing the molten zone down the solid sample to be purified (**Figures 1A and 1B**). Subsequent passes of the molten zone increase the purity without requiring any handling.

The technique of purification by zone melting is commonly called zone refining. Any substance that can be melted and solidified and exhibits a difference in impurity concentration in the liquid and solid states at the point of solidification can be purified by this method. The impurities redistribute, being displaced toward one end with corresponding purification of the portion being traversed by the molten zone. Though zone melting is largely restricted to

systems exhibiting liquid–solid transformation, successful refining has also been carried out where vapor–solid and even solid–solid transformations take place. In cases where any of these equilibria are not favorable for an impurity, zone refining may be combined with other techniques to achieve the desired purity level.

It is essential to distinguish between zone refining and other common purification techniques. The process in which the whole of the charge is melted and gradually solidified unidirectionally is referred to as normal freezing. This may result in a mass of small crystals that may have entrapped liquid. Therefore, slow growth rates are required to secure a continuous and smooth solid–liquid interface during freezing from solvent or melt. Although many difficult separations, such as isolation of radium and separation of lanthanoids, have been achieved by repeated, fractional crystallization, zone refining is superior as it decreases the effort of making such repetitions.

The main difference between the two techniques is that in zone refining only a part of the charge is melted at any time. This change alone tremendously increases the efficiency of crystallization as a separation and purification method. An impurity travels with or opposite to the movement of the zone depending, respectively, on whether it lowers or raises the melting point of the substance to be purified. In this way the impurities are concentrated in one or

**Figure 1** Schematic diagram of a horizontal (A) and vertical (B) configuration of the zone melting process. 1, Resolidified zone; 2, unmelted zone; 3, molten zone; 4, heater.

the other end of the charge, thereby purifying the remainder. The degree of purification increases with each increase in the number of passes defined as the number of times a single zone passes through the charge. Pfann, working on the purification of germanium for making transistors, was able to produce this element having less than 1 part of impurity in  $10^{10}$  parts of germanium.

Besides purification, zone melting is useful in distributing any impurity uniformly throughout a system and in producing single crystals. Thus, precisely controlled discontinuities in impurity concentration, such as p-n or n-p-n junctions in semiconductors can be made in order to produce basic building blocks for transistors and solid diodes. Since zone refining can remove as well as concentrate the desired impurity, it can be used as a powerful analytical tool for detecting and determining impurities unobservable by conventional means.

## Theory of Zone Refining

Consider a sample consisting of bulk component B contaminated with impurity I, the concentration of which is  $C_0$ . I is analogous to the solute and B to the solvent. The sample, also called 'the charge', is taken in the form of a bar or rod of length  $L$  ( $\leq 0.5$  m). The heating zone, in the form of a narrow ring of width  $l$  capable of being heated to temperatures above the melting point of the sample, is positioned around the sample rod (Figures 1A and 1B). Generally, the heating zone is mobile and the sample is kept stationary, but the refining process can also be carried out by holding the heating zone stationary and moving the sample. Means of heating include electrical resistance coils, electric arc, electron beam, induction coil, lasers, plasma, radiant energy, and solar energy. Movement of the heating zone ( $4 \text{ cm h}^{-1}$ ) along the sample produces a molten zone at the front and a solid zone at the rear. If the solute lowers the melting point of the solvent, its concentration in the freezing solid is lower than in the liquid. If the solute raises the melting point, the resolidified mass is more impure than the liquid phase. Thus, the freezing interface rejects certain solutes and attracts others.

The measure of concentration of the impurity in the liquid phase is given by the distribution coefficient  $k$ , defined as the ratio of concentration of impurity I in the just-forming solid phase to that in the liquid phase, i.e.,

$$k = C_S/C_L$$

When the solid and liquid phases are in equilibrium, then  $k = k_0$ , where  $k_0$  is the equilibrium distribution

**Figure 2** A schematic impurity distribution for single-pass zone refining.

coefficient. When  $k_0 < 1$  addition of solute lowers the melting point; conversely, if the melting point is raised by the addition of solute then  $k_0 > 1$ . Assuming  $k < 1$ , the concentration  $C$  of the impurity I in the resolidified mass at a distance  $x$  from the starting end is given by

$$C = C_0[1 - (k)e^{-kx/l}]$$

where  $C_0$  is the concentration at  $x=0$  (Figure 2). In such a case, moving the heating zone from left to right (Figure 1A) concentrates impurities on the right-hand side. Consequently, a second pass of the heater will result in further purification of the sample by depleting impurities from the left-hand side and accumulating these on the extreme right of the sample rod. This enrichment continues at a decreasing rate until its concentration attains a value  $C_0/k$ . From this point on, the concentrations entering and leaving the zone are equal and the concentration of freezing solid remains  $C_0$ . In the last portion of the charge equal to the zone length  $l$ , the impurity concentration is more than in the original sample (Figure 2).

In the same way as higher purity is achieved by repeated crystallizations or separation and recombination of fractions in fractional crystallization, purity can be increased in zone refining by accumulating impurities in one or other end by multipass zone refining. This can be achieved either by repeated zoning by a single heater or better, by using a multiple heater arrangement (Figure 3). This eliminates all kinds of handling procedures. Another advantage of multipass zoning is the small size of the molten region, which ensures minimal contamination by the container or atmosphere. After several passes, the impurity concentration approaches a steady state or ultimate distribution.

**Figure 3** Multipass zone refining.

## Factors Affecting Zone Refining

### Width of Heating Zone

The width of the heating zone, defined as the length of the solid melted to form the zone (and not the length of the molten zone), is one of the most important operational parameters. It is desirable to express the length of the sample rod  $l$  as a multiple  $n$  of the zone width, i.e.,

$$n = L/l$$

Thus, the greater the value of  $n$ , the greater the number of zone passes required to approach the ultimate distribution. After  $n$  passes, each successive additional pass produces less additional purification. In practice,  $n < 5$  is not very useful. Further, the interzone spacing  $i$  is generally of the order of the zone width  $l$ , though for high thermal conductivity materials like copper, it may be several zone widths.

### Zone Traverse Velocity

Diffusion coefficients of the solid and impurities, and impurity rejection and its transport away from the solidifying face, are governing factors that determine zone travel speed. The rate of solidification consequent upon the speed of zone travel must be much more than the rate of solid diffusion but not so fast as to prevent efficient diffusion of the impurity into the molten zone. Mechanical aids like stirring, to facilitate liquid diffusion, increases the efficiency of the process and permits an increase in zone speed by a factor of 10 or more. However, at high freezing rates, dendrites are formed which entrap liquid, and at somewhat lower rates, prismatic substructures are formed. In fact, for attaining the highest purity in the shortest time, for a given value of  $k$  it is necessary to set the ratio  $n/f$  to its smallest possible value,  $f$  being the heating zone traverse speed. Also, the ratio  $G/R$  (temperature gradient/growth rate) must be less than

the critical value; the former is related to zone width and the latter to zone speed.

### Matter Transport in Zone Melting

The process of zone refining is primarily based on the transport of impurities in one or other direction. The driving force in matter transport is provided by the difference in densities between the solid and liquid phases. If the density of the liquid formed on melting the solid is higher, then the matter is transported in the direction of zone travel. Conversely, if expansion occurs on melting, the matter is transported in the opposite direction to the movement of the heating zone. In situations like this, matter transport is avoided by tilting the sample ingot. The critical angle of tilt is such that the liquid surface at the trailing end is at the same height as that of the original solid before it was molten.

## Factors Influencing the Design of Zone Refining Equipment

These factors include:

1. The nature of the process, whether batch, semi-continuous, or continuous.
2. The yield of purified material to be obtained in relation to time and expense.
3. The chemical and physical properties of the material to be purified and to a lesser extent the properties of the impurities.
4. The properties of the container material with reference to the melting point, thermal conductivity, porosity, and thermal expansion of the material to be purified. Conventional container materials used in zone refining include plastics (e.g., polytetrafluoroethylene), metals, glass, silica, mullite ( $\text{Al}_2\text{Si}_2\text{O}_{13}$ ), alumina, and graphite. In some cases compounds like zirconia ( $\text{ZrO}_2$ ), beryllia ( $\text{BeO}$ ), and various fluorides, silicides, and nitrides are used. Silicon nitride is of special interest in view of its low coefficient of expansion, high temperature strength, resistance to thermal shocks, inertness, and non-wettability by metals. If the properties of the container material are incompatible with those of the sample, refining may be carried out by the unsupported floating zone method (FZM) (see below).
5. The atmosphere in the vessel surrounding the charge.
6. The traversing mechanism for transport of the molten zone(s). The choice lies between moving the charge and moving the heat source. The former has practical limitations where controlled atmosphere and temperature are involved. It is possible to move both the bar and the atmosphere

containment vessel simultaneously. The stirring of the molten zone by mechanical means during zoning, in order to aid diffusion, is more easily achieved if the heating zone is static and the charge is made to move.

## Modifications of Zone Refining

### Continuous Zone Refining

Zone refining, as outlined above, is a multistage batch technique in which successive operations are performed on a single batch of sample. The main limitation of such a procedure is the decrease in efficiency of zone passes as their number increases. Thus, ultimate purity is obtainable only at a prohibitive cost of time and money.

To circumvent the various limitations of the basic technique, several continuous zone refining methods have been developed in which feed enters at one point in the sample while the product and waste leave at other points (Figure 4). The effect of countercurrent movement of solid and liquid phases is achieved by the movement of molten zones. In addition to the horizontal continuous refiner, the zone void vertical refiner and zone transport refiner are other modifications of this class. Cross-flow zone refiners and rotating drum multistage crystallizers based on the above principle are mainly used in growing single crystals rather than in purification of materials.

### Zone Leveling

It is virtually impossible to obtain a uniform concentration of a soluble impurity from one end to the other of a crystal grown from the melt by a conventional zone melting method because the separating crystals differ in composition from that of the melt. Zone leveling denotes a group of zone melting methods that aim to produce a uniform, or level,

distribution of impurity in the charge. In this method, the initial concentration in the first zone length is arranged to be  $C_0/k$  and in the remainder,  $C_0$ . Once this condition is met, the impurity concentrations entering and leaving the heat zone remain constant until the zone reaches the end of the ingot and normal freezing commences. The method is highly valuable in producing homogeneous single crystals having a uniform concentration of impurity, for example, crystals of a germanium-rich germanium-silicon alloy. This alloy is highly prone to segregation;  $k$  for silicon in germanium is  $\sim 3$ .

Another freezing technique has been developed in which the distribution of solute (i.e., impurity) is perturbed during freezing. This technique, called the method of perturbing the concentration, has led to the production of solid electronic devices having p-n and n-p-n junctions.

### Floating Zone Method

The FZM is a melt growth technique that does not require the use of a crucible. Thus, sample contamination by the container is not a problem. A vertical sample is heated with a focused laser light source or another heat source that can produce a molten zone capable of being held in place by surface tension. The molten zone can be seeded to produce oriented or single crystals. A miniaturized version of FZM called a laser-heated pedestal growth method uses a  $\text{CO}_2$  laser operating at  $10.6\text{ }\mu\text{m}$ ; in certain cases several lasers have also been used. The source rod is produced by cold pressing or sintering. To start, a molten region is formed at the top of the source rod. The seed rod, which may be of an inert or refractory material like platinum or indium, or polycrystalline or a single crystal of interest, is introduced into the melt and slowly withdrawn to initiate the crystal growth. The method was first applied to grow crystals of superconducting material of composition  $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_8$ . Another version of the FZM applied to incongruently melting materials is called the traveling solvent float zone (TSFZ) method. In this method the composition of the feed rod is that of the desired final product. Single superconducting crystals of  $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$  are reported to have been prepared by TSFZ.

### Liquid Encapsulation

Materials with volatile components are taken in an enclosed system so as to maintain the vapor pressure of the volatile constituents equal to or more than the equilibrium dissociation pressure over the melt. The loss of the volatile constituent is prevented simply by maintaining an inert gas pressure greater than

Figure 4 Continuous zone refining process.

the equilibrium dissociation vapor pressure of the volatile component. It is desirable that a liquid encapsulant should be less dense than the melt, be optically transparent, have a low viscosity at the melting point of the sample, and be stable and non-reactive with melt, crucible, and environment.  $B_2O_3$  is the encapsulant of choice above  $1000^\circ\text{C}$ . Below  $800^\circ\text{C}$ ,  $BaCl_2$ ,  $CaCl_2$ , and  $CaCl_2 + KCl$  are used and at still lower temperatures  $LiI + KI$  is used as an encapsulant for zone refining of  $CdSnAs_3$ . Certain organic acids are used for growing bismuth crystals at  $\sim 150^\circ\text{C}$ . On the other hand, high-pressure float zone melting is employed for achieving high purity of dissociating samples like GaP.

Where sample availability is in the range of a few micrograms to a few milligrams, microscale zone refining is very advantageous. Besides processing very small quantities, the operational time is drastically decreased because a large number of heating zones is used and the zone speed can be increased because of the more diffusive mixing achieved.

### Solution Zone Refining

Solution zone refining, also called traveling heater zone refining (THZR), is identical to zone refining. It consists of a liquid zone ( $\sim 1\text{ cm}$  thick) of a concentrated solution containing the phase to be refined as solute; the solvent should be such as to dissolve the solute and the impurities but to be insoluble in the solid solute phase. This process is particularly promising for purification of materials that decompose on melting, have very high melting points, have a high vapor pressure at the melting point, and are highly reactive. By using THZR, purification can be achieved at a much lower temperature than is normally possible.

### Other Methods

Thin alloy zone crystallization (TAZC) and temperature gradient zone melting (TGZM), in which the driving force is, respectively, an electrochemical potential and a temperature gradient, have also been developed based on the principle of zone refining. An alloy of composition 80% indium and 20% antimony (m.p.  $425^\circ\text{C}$ ) for refining thin layers of InSb has been prepared by TAZC whereas TGZM has been used in fabricating semiconductor junctions, and joining and growing single crystals.

## Applications of Zone Refining

Zone refining, an extremely simple technique in principle, provides an excellent means of preparing ultrapure crystalline materials. Handling of the

material and its consequent contamination is kept to an absolute minimum. Further, the use of a controlled atmosphere or vacuum in the system removes the danger of atmospheric contamination or reaction with components of the air. Besides purification, the importance of zone melting methods lies in the uniform distribution of the desired impurity throughout a single crystal, a problem which remained unsolved for a long time. Thus, precisely controlled discontinuities in impurity concentration can be made to produce p-n or n-p-n junctions in semiconductors. Further, joining single crystals and measuring diffusivities in liquids can also be achieved. Some examples of the applications of zone refining are given below.

### Refining of Metals

A large number of metals have been obtained in a state of ultrapurity by zone refining. Quantification of impurities is done by measuring the ratio of resistivities at two different concentrations of the impurity. Uranium is purified by zone refining in a uranium oxide boat and an atmosphere of purified argon; a travel rate of  $6\text{ mm h}^{-1}$  was found to be the most satisfactory. By starting from a relatively pure material, a 90% decrease in iron and carbon content is achieved; oxygen and nitrogen are also removed by vaporization. A final purity  $>99.99\%$  is obtained.

### Refining of Semiconductors

**Elemental semiconductors** Germanium has been widely used for semiconductor diodes and transistors. Six zone passes through an ingot of the purest available germanium sufficed to decrease the concentration of impurities to 1 atom in  $10^{10}$  atoms of germanium.

Ultrapure silicon is not only important for transistors, it is also required for solar batteries. Zone refining of silicon using a quartz boat is unable to remove the last traces of boron except when a chemical purification is simultaneously applied. The reactivity of molten silicon creates problems of contamination with oxygen. For higher purity, the floating zone technique has been used to quantify the concentration of boron, an electron acceptor, and phosphorus, an electron donor. The electrical conductivity measured as a function of distance along the rod is found to be proportional to the difference in concentration of boron and phosphorus; their concentration after refining is of the order of  $10^3\text{ atoms cm}^{-3}$ .

Copper impurity in selenium is related to a trapping center in CdSe. After more than eight passes, copper accumulates at one end. Its concentration at

the other end was below the detectable limit;  $k$  for copper is  $<1$ .

**Compound semiconductors** A (III–V) compound, InSb, is of particular interest in view of its highest electron mobility. In its preparation, zone refining of the compound, of the components, or both, may be utilized. During zone refining, the optical energy gap of InSb decreases from 0.39 eV for relatively impure material to 0.18 eV for an extensively refined sample. The electrical conductivity and Hall coefficient of pure and tellurium-doped InSb were measured as functions of temperature from 90 to 470 K. From the analytical standpoint, it was possible to identify the critical impurities in InSb. Both tellurium and zinc are present. The former, a donor, lowers the melting point and is slower to segregate but is removed by zone refining, while zinc, an acceptor, raises the melting point and is removed only on electroplating.

Thallium bromide semiconductor for X-ray and  $\gamma$ -ray detectors is purified by multipass zone refining. A vacuum-deposited thin film of TlBr is used as a single photon detector and in X-ray imaging including xeroradiography.

#### Preparation of Films and Single Crystals of Superconductors

Several complex compounds have been investigated for their superconducting properties. These usually comprise oxides of a lanthanoid, an alkaline earth metal, and a transition metal. Superconducting properties of such complex oxide systems are very sensitive to the presence of impurities. Films of the Y–Ba–Cu–O system with a critical temperature for superconducting transition of 80 K have been obtained by zone crystallization. Single crystals of  $\text{Bi}_2\text{Sr}_2\text{CaCuO}_8$  are obtained by TSFZ. Measurement of the superconducting properties of various parts of the crystal shows that the later grown part exhibits semiconducting behavior. After 1 day of annealing, homogeneous crystals are obtained. Large single crystals of Bi-2212 superconducting along the  $c$ -axis have been prepared by FZM.

#### Refining of Organic and Inorganic Compounds

Many organic and inorganic compounds have been zone refined. Since the physical properties of compounds differ significantly from metals, these require different apparatus. The low thermal diffusivity requires artificial cooling between zones. Low chemical diffusivity makes agitation of the liquid desirable; agitation also ensures better heat transfer to the liquid.

Ultrapure crystals of nitrobenzene for nonlinear optical devices are prepared by zone refining of the fractionally distilled, purified sample. Single crystals of  $m$ -nitroaniline for use as waveguides in optical second-harmonic generation are produced by zone melting crystallization using a ridge heater. Sodium nitrate has been purified by infrared laser-assisted zone refining. Besides a large number of hydrocarbons, fatty acids, alcohols, nitrogen- and sulfur-containing organic compounds, halides, and nitrates have also been purified by various zone refining methods.

#### Analytical Applications

Zone refining is a powerful tool for separation and concentration. Following preconcentration, conventional analytical techniques are used to identify and quantify the impurity. This has enabled certain observed abnormalities in properties to be correlated with the presence of impurities in ultratrace amounts that had earlier remained undetected. In another version, the distribution coefficient,  $k$ , of a metallic solute is determined by adding its radioisotope under the conditions of the zoning experiment. If the concentration of the nonradioactive form of the solute in the starting material is measurable by an available analytical technique but subsequently falls below the detection limit after refining, its final concentration can still be calculated from the value of  $k$  and the zone refining curves.

## APPENDIX 1. NOMENCLATURE OF ANALYTICAL SCIENCE

The nomenclature used in Analytical Chemistry, and therefore in this encyclopedia, is that agreed and published by the International Union of Pure and Applied Chemistry (IUPAC) after deliberations by numerous specialist Commissions and Working Parties. The more fundamental definitions and values are to be found in *Quantities, Units and Symbols in Physical Chemistry* (1993), 2nd edn., Oxford: Blackwell Scientific Publications, prepared for publication by Mills I, Cvitas T, Homann K, *et al.* (the so-called Green Book). Some of the information from this publication is included in these appendices, as are the currently accepted values of atomic weights, isotopic, composition, etc., which are the responsibility of the Inorganic Chemistry Division.

The specialized terminology of Analytical Chemistry has been the enduring responsibility of the Analytical Division of IUPAC. The terminology is to be found in the *Compendium of Analytical Nomenclature. Definitive Rules 1997* (1998), 3rd edn., Oxford: Blackwell Scientific Publications, prepared for publication by Inczédy J, Lengyel T, and Ure AM (the so-called Orange Book). Nomenclature, of course, reflects the relentless advance of science, so new and revised definitions are continually being published, initially for consultation by the international community, in *Pure and Applied Chemistry*.

Proposed IUPAC nomenclature is scrutinized for validity, accuracy and consistency across all branches of Chemistry, and over Science generally, by IUPAC's Interdivisional Committee on Terminology, Nomenclature and Symbols. The committee has representation from other International Scientific Unions: Biochemistry and Molecular Biology (IUBMB), Crystallography (IUCr), Nutritional Sciences (IUNS), Pharmacology (IUPHAR) and Pure and Applied Physics (IUPAP), and from the Bureau International des Poids et Mesures (BIPM) and the International Organization for Standardization (ISO), as well as Divisional and other representatives of IUPAC.

Details of current activities of IUPAC can be found at <http://www.iupac.org>

# APPENDIX 3. DEFINITIONS AND SYMBOLS FOR UNITS

© 1993, Blackwell Science. Published by Elsevier Ltd. All rights reserved.

## The International System of Units (SI)

The International System of units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built from seven *SI base units*, one for each of the seven dimensionally independent base quantities: the meter, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes*, may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units.

## Definitions of the SI Base Units

**Meter:** The meter is the length of path travelled by light in vacuum during a time interval of  $1/299\,792\,458$  of a second (17th CGPM, 1983).

**Kilogram:** The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

**Second:** The second is the duration of  $9\,192\,631\,770$  periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the caesium-133 atom (13th CGPM, 1967).

**Ampere:** The ampere is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross-section, and placed 1 meter apart in vacuum, would produce between these conductors a force equal to  $2 \times 10^{-7}$  newton per meter of length (9th CGPM, 1948).

**Kelvin:** The kelvin, unit of thermodynamic temperature, is the fraction  $1/273.16$  of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

**Mole:** The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, other particles, or specified groups of such particles (14th CGPM, 1971).

### Examples of the use of the mole

1 mol of  $\text{H}_2$  contains  $\sim 6.022 \times 10^{23}$   $\text{H}_2$  molecules, or  $12.044 \times 10^{23}$  H atoms

1 mol of  $\text{HgCl}$  has a mass of 236.04 g

1 mol of  $\text{Hg}_2\text{Cl}_2$  has a mass of 472.08 g

1 mol of  $\text{Hg}_2^{2+}$  has a mass of 401.18 g and a charge of 192.97 kC

1 mol of  $\text{Fe}_{0.91}\text{S}$  has a mass of 82.88 g

1 mol of  $\text{e}^-$  has a mass of 548.60  $\mu\text{m}$  and a charge of  $-96.49$  kC

1 mol of photons whose frequency is  $5 \times 10^{14}$  Hz has energy of  $\sim 199.5$  kJ

**Candela:** The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency  $540 \times 10^{12}$  hertz and that has a radiant intensity in that direction of  $(1/683)$  watt per steradian (16th CGPM, 1979).

## Names and Symbols for the SI Base Units

The symbols listed here are internationally agreed and should not be changed in other languages or scripts.

<i>Physical quantity</i>	<i>Name of SI unit</i>	<i>Symbol for SI unit</i>
Length	Meter	m
Mass	Kilogram	kg
Time	Second	s
Electric current	Ampere	A
Thermodynamic temperature	Kelvin	K
Amount of substance	Mole	mol
Luminous intensity	Candela	cd

## SI Derived Units with Special Names and Symbols

<i>Physical quantity</i>	<i>Name of SI unit</i>	<i>Symbol for SI unit</i>	<i>Expression in terms of SI base units</i>
Frequency <sup>a</sup>	Hertz	Hz	$s^{-1}$
Force	Newton	N	$kg\,s^{-2}$
Pressure, stress	Pascal	Pa	$N\,m^{-2} = m^{-1}\,kg\,s^{-2}$
Energy, work, heat	Joule	J	$N\,m = m^2\,kg\,s^{-2}$
Power, radiant flux	Watt	W	$J\,s^{-1} = m^2\,kg\,s^{-3}$
Electric charge	Coulomb	C	$A\,s$
Electric potential, electromotive force	Volt	V	$J\,C^{-1} = m^2\,kg\,s^{-3}\,A^{-1}$
Electric resistance	Ohm	$\Omega$	$V\,A^{-1} = m^2\,kg\,s^{-3}\,A^{-2}$
Electric conductance	Siemens	S	$\Omega^{-1} = m^{-2}\,kg^{-1}\,s^3\,A^2$
Electric capacitance	Farad	F	$C\,V^{-1} = m^{-2}\,kg^{-1}\,s^4\,A^2$
Magnetic flux density	Tesla	T	$V\,s\,m^{-2} = kg\,s^{-2}\,A^{-1}$
Magnetic flux	Weber	Wb	$V\,s = m^2\,kg\,s^{-2}\,A^{-1}$
Inductance	Henry	H	$V\,A^{-1}\,s = m^2\,kg\,s^{-2}\,A^{-2}$
Celsius temperature <sup>b</sup>	Degree Celsius	$^{\circ}C$	K
Luminous flux	Lumen	lm	$cd\,sr$
Illuminance	Lux	lx	$cd\,sr\,m^{-2}$
Activity <sup>c</sup> (radioactive)	Becquerel	Bq	$s^{-1}$
Absorbed dose <sup>c</sup> (of radiation)	Gray	Gy	$J\,kg^{-1} = m^2\,s^{-2}$
Dose equivalent <sup>c</sup> (dose equivalent index)	Sievert	Sv	$J\,kg^{-1} = m^2\,s^{-2}$
Plane angle <sup>d</sup>	Radian	rad	$1 = m\,m^{-1}$
Solid angle <sup>d</sup>	Steradian	sr	$1 = m^2\,m^{-2}$

<sup>a</sup> For radial (angular) frequency and for angular velocity the unit  $rad\,s^{-1}$ , or simply  $s^{-1}$ , should be used, and this may *not* be simplified to Hz. The unit Hz should be used *only* for frequency in the sense of cycles per second.

<sup>b</sup> The Celsius temperature  $\theta$  is defined by the equation

$$\theta/^{\circ}C = T/K - 273.15$$

The SI unit of Celsius temperature is the degree Celsius,  $^{\circ}C$ , which is equal to the kelvin, K.  $^{\circ}C$  should be treated as a single symbol, with no space between the  $^{\circ}$  sign and the letter C. (The symbol  $^{\circ}K$ , and the symbol  $^{\circ}$ , should no longer be used).

<sup>c</sup> The units becquerel, gray and sievert are admitted for reasons of safeguarding human health.

<sup>d</sup> The units radian and steradian are described as 'SI supplementary units'. However, in chemistry, as well as in physics, they are usually treated as dimensionless derived units, and this was recognized by CIPM in 1980. Since they are then of dimension 1, this leaves open the possibility of including them or omitting them in expressions of SI derived units. In practice, this means that rad and sr may be used when appropriate and may be omitted if clarity is not lost thereby.

## SI Derived Units for Other Quantities

This Table gives examples of other SI derived units; the list is merely illustrative.

<i>Physical quantity</i>	<i>Expression in terms of SI base units</i>	
Area	$\text{m}^2$	
Volume	$\text{m}^3$	
Speed, velocity	$\text{m s}^{-1}$	
Angular velocity	$\text{s}^{-1}, \text{rad s}^{-1}$	
Acceleration	$\text{m s}^{-2}$	
Moment of force	$\text{Nm}$	$= \text{m}^2 \text{kg s}^{-2}$
Wavenumber	$\text{m}^{-1}$	
Density, mass density	$\text{kg m}^{-3}$	
Specific volume	$\text{m}^3 \text{kg}^{-1}$	
Amount concentration <sup>a</sup>	$\text{mol m}^{-3}$	
Molar volume	$\text{m}^3 \text{mol}^{-1}$	
Heat capacity, entropy	$\text{J K}^{-1}$	$= \text{m}^2 \text{kg s}^{-2} \text{K}^{-1}$
Molar heat capacity, molar entropy	$\text{J K}^{-1} \text{mol}^{-1}$	$= \text{m}^2 \text{kg s}^{-2} \text{K}^{-1} \text{mol}^{-1}$
Specific heat capacity, specific entropy	$\text{J K}^{-1} \text{kg}^{-1}$	$= \text{m}^2 \text{s}^{-2} \text{K}^{-1}$
Molar energy	$\text{J mol}^{-1}$	$= \text{m}^2 \text{kg s}^{-2} \text{mol}^{-1}$
Specific energy	$\text{J kg}^{-1}$	$= \text{m}^2 \text{s}^{-2}$
Energy density	$\text{J m}^{-3}$	$= \text{m}^{-1} \text{kg s}^{-2}$
Surface tension	$\text{N m}^{-1} = \text{J m}^{-2}$	$= \text{kg s}^{-2}$
Heat flux density, irradiance	$\text{W m}^{-2}$	$= \text{kg s}^{-3}$
Thermal conductivity	$\text{W m}^{-1} \text{K}^{-1}$	$= \text{m kg s}^{-3} \text{K}^{-1}$
Kinematic viscosity, diffusion coefficient	$\text{m}^2 \text{s}^{-1}$	
Dynamic viscosity	$\text{N s m}^{-2} = \text{Pas}$	$= \text{m}^{-1} \text{kg s}^{-1}$
Electric charge density	$\text{C m}^{-3}$	$= \text{m}^{-3} \text{s A}$
Electric current density	$\text{A m}^{-2}$	
Conductivity	$\text{S m}^{-1}$	$= \text{m}^{-3} \text{kg}^{-1} \text{s}^3 \text{A}^2$
Molar conductivity	$\text{S m}^2 \text{mol}^{-1}$	$= \text{kg}^{-1} \text{mol}^{-1} \text{s}^3 \text{A}^2$
Permittivity	$\text{F m}^{-1}$	$= \text{m}^{-3} \text{kg}^{-1} \text{s}^4 \text{A}^2$
Permeability	$\text{H m}^{-1}$	$= \text{m kg s}^{-2} \text{A}^{-2}$
Electric field strength	$\text{V m}^{-1}$	$= \text{m kg s}^{-3} \text{A}^{-1}$
Magnetic field strength	$\text{A m}^{-1}$	
Luminance	$\text{cd m}^2$	
Exposure (X- and $\gamma$ -rays)	$\text{C kg}^{-1}$	$= \text{kg}^{-1} \text{s A}$
Absorbed dose rate	$\text{Gy s}^{-1}$	$= \text{m}^2 \text{s}^{-3}$

<sup>a</sup>The words 'amount concentration' are an abbreviation for 'amount-of-substance concentration'. When there is not likely to be any ambiguity this quantity may be called simply 'concentration'.

## SI Prefixes

To signify decimal multiples and submultiples of SI units the following prefixes may be used.

<i>Submultiple</i>	<i>Prefix</i>	<i>Symbol</i>	<i>Multiple</i>	<i>Prefix</i>	<i>Symbol</i>
$10^{-1}$	deci	d	10	deca	da
$10^{-2}$	centi	c	$10^2$	hecto	h
$10^{-3}$	milli	m	$10^3$	kilo	k
$10^{-6}$	micro	$\mu$	$10^6$	mega	M
$10^{-9}$	nano	n	$10^9$	giga	G
$10^{-12}$	pico	p	$10^{12}$	tera	T
$10^{-15}$	femto	f	$10^{15}$	peta	P
$10^{-18}$	atto	a	$10^{18}$	exa	E
$10^{-21}$	zepto	z	$10^{21}$	zetta	Z
$10^{-24}$	yocto	y	$10^{24}$	yotta	Y

Prefix symbols should be printed in roman (upright) type with no space between the prefix and the unit symbol.

*Example* kilometer, km

When a prefix is used with a unit symbol, the combination is taken as a new symbol that can be raised to any power without the use of parentheses.

*Examples*  $1 \text{ cm}^3 = (0.01 \text{ m})^3 = 10^{-6} \text{ m}^3$   
 $1 \mu\text{s}^{-1} = (10^{-6} \text{ s})^{-1} = 10^{-6} \text{ s}^{-1}$   
 $1 \text{ V cm}^{-1} = 100 \text{ V m}^{-1}$   
 $1 \text{ mmol dm}^{-3} = 1 \text{ mol m}^{-3}$

A prefix should never be used on its own, and prefixes are not to be combined into compound prefixes.

*Example* pm, not  $\mu\mu\text{m}$

The names and symbols of decimal multiples and submultiples of the SI base unit of mass, the kg, which already contains a prefix, are constructed by adding the appropriate prefix to the word gram and symbol g.

*Examples* mg, not  $\mu\text{kg}$ ; Mg, not kkg

The SI prefixes are not to be used with  $^{\circ}\text{C}$ .

ISO has recommended standard representations of the prefix symbols for use with limited character sets.

## Units in Use Together with the SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as milliliter, ml; millibar, mbar; megaelectronvolt, MeV; kilotonne, kt. A more extensive list of non-SI units, with conversion factors to the corresponding SI units, is given in the appendix, Conversion of Units.

<i>Physical quantity</i>	<i>Name of unit</i>	<i>Symbol for unit</i>	<i>Value in SI units</i>
Time	Minute	min	60 s
Time	Hour	h	3 600 s
Time	Day	d	86 400 s
Plane angle	Degree	$^{\circ}$	$(\pi/180) \text{ rad}$
Plane angle	Minute	'	$(\pi/10\,800) \text{ rad}$
Plane angle	Second	"	$(\pi/648\,000) \text{ rad}$
Length	Ångström <sup>a</sup>	Å	$10^{-10} \text{ m}$
Area	Barn	b	$10^{-28} \text{ m}^2$
Volume	Litre	l, L	$\text{dm}^3 = 10^{-3} \text{ m}^3$
Mass	Tonne	t	$\text{Mg} = 10^3 \text{ kg}$
Pressure	Bar <sup>a</sup>	bar	$10^5 \text{ Pa} = 10^5 \text{ N m}^{-2}$
Energy	Electronvolt <sup>b</sup>	eV ( $= e \times V$ )	$\approx 1.602\,18 \times 10^{-19} \text{ J}$
Mass	Unified atomic mass unit <sup>b,c</sup>	u ( $= m_{\text{a}}(^{12}\text{C})/12$ )	$\approx 1.660\,54 \times 10^{-27} \text{ kg}$

<sup>a</sup>The ångström and the bar are approved by CIPM for 'temporary use with SI units', until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

<sup>b</sup>The values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants  $e$  (for the electronvolt) and  $N_{\text{A}}$  (for the unified atomic mass unit), which are determined by experiment. See appendix, Fundamental Constants.

<sup>c</sup>The unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

## Atomic Units

For the purposes of quantum mechanical calculations of electronic wavefunctions, it is convenient to regard certain fundamental constants (and combinations of such constants) as though they were units. They are customarily called *atomic units* (abbreviated: au), and they may be regarded as forming a coherent system of units for the calculation of electronic properties in theoretical chemistry, although there is no authority from

CGPM for treating them as units. The first five atomic units in the table below have special names and symbols. Only four of these are independent; all others may be derived by multiplication and division in the usual way, and the table includes a number of examples.

The relation of atomic units to the corresponding SI units involves the values of the fundamental physical constants, and is therefore not exact. The numerical values in the table are based on the estimates of the appendix, Fundamental Constants. The numerical results of calculations in theoretical chemistry are frequently quoted in atomic units, or as numerical values in the form (*physical quantity*)/(*atomic unit*), so that the reader may make the conversion using the current best estimates of the physical constants.

<i>Physical quantity</i>	<i>Name of unit</i>	<i>Symbol for unit</i>	<i>Value of unit in SI</i>
Mass	Electron rest mass	$m_e$	$9.109\,389\,7\,(54) \times 10^{-31} \text{ kg}$
Charge	Elementary charge	$e$	$1.602\,177\,33\,(49) \times 10^{-19} \text{ C}$
Action	Planck constant/ $2\pi^a$	$\hbar$	$1.054\,572\,66\,(63) \times 10^{-34} \text{ J s}$
Length	Bohr <sup>a</sup>	$A_0$	$5.291\,772\,49\,(24) \times 10^{-11} \text{ m}$
Energy	Hartree <sup>a</sup>	$E_h$	$4.359\,748\,2\,(26) \times 10^{-18} \text{ J}$
Time		$\hbar/E_h$	$2.418\,884\,334\,1\,(29) \times 10^{-17} \text{ s}$
Velocity <sup>b</sup>		$a_0 E_h/\hbar$	$2.187\,691\,42\,(10) \times 10^6 \text{ m s}^{-1}$
Force		$E_h/a_0$	$8.238\,729\,5\,(25) \times 10^{-8} \text{ N}$
Momentum, linear		$\hbar/a_0$	$1.992\,853\,4\,(12) \times 10^{-24} \text{ N s}$
Electric current		$e E_h/\hbar$	$6.623\,621\,1\,(20) \times 10^{-3} \text{ A}$
Electric field		$E_h/e a_0$	$5.142\,208\,2\,(15) \times 10^{-11} \text{ V m}^{-1}$
Electric dipole moment		$e a_0$	$8.478\,357\,9\,(26) \times 10^{-30} \text{ C m}$
Magnetic flux density		$\hbar/e a_0^2$	$2.350\,518\,08\,(71) \times 10^5 \text{ T}$
Magnetic dipole moment <sup>c</sup>		$e \hbar/m_e$	$1.854\,803\,08\,(62) \times 10^{-23} \text{ J T}^{-1}$

<sup>a</sup>  $\hbar = h/2\pi$ ;  $a_0 = 4\pi\epsilon_0\hbar^2/m_e e^2$ ;  $E_h = \hbar^2/m^3 a_0^2$ .

<sup>b</sup> The numerical value of the speed of light, when expressed in atomic units, is equal to the reciprocal of the fine structure constant  $\alpha$ ;  $c/(\text{au of velocity}) = c\hbar/a_0 E_h = \alpha^{-1} \approx 137.035\,989\,5\,(61)$ .

<sup>c</sup> The atomic unit of magnetic dipole moment is twice the Bohr magneton,  $\mu_B$ .

## Dimensionless Quantities

Values of dimensionless physical quantities, more properly called ‘quantities of dimension one’, are often expressed in terms of mathematically exactly defined values denoted by special symbols or abbreviations, such as % (percent) and ppm (part per million). These symbols are then treated as units, and are used as such in calculations.

### Fractions (Relative Values, Yields, and Efficiencies)

Fractions such as relative uncertainty, mole fraction  $x$  (also called amount fraction, or number fraction), mass fraction  $w$ , and volume fraction  $\phi$ , are sometimes expressed in terms of the symbols summarized in the table below.

<i>Name</i>	<i>Symbol</i>	<i>Value</i>	<i>Examples</i>
Percent	%	$10^{-2}$	The isotopic abundance of carbon-13 expressed as a mole fraction is $x = 1.1\%$
Part per million	ppm	$10^{-6}$	The relative uncertainty in the Planck constant $h$ ( $= 6.626\,075\,5\,(40) \times 10^{-34} \text{ J s}$ ) is 0.60 ppm The mass fraction of impurities in a sample of copper was found to be less than 3 ppm, $w < 3 \text{ ppm}$

These multiples of the unit one are not part of the SI and ISO recommends that these symbols should never be used. They are also frequently used as units of ‘concentration’ without a clear indication of the type of fraction implied (e.g., mole fraction, mass fraction or volume fraction). To avoid ambiguity they should only be used in a context where the meaning of the quantity is carefully defined. Even then, the use of an appropriate SI unit ratio may be preferred.

**Deprecated Usage**

Adding extra labels to ppm and similar symbols, such as ppmv (meaning ppm by volume) should be avoided. Qualifying labels may be added to symbols for physical quantities, but never to units.

The symbols % and ppm should not be used in combination with other units. In table headings and in labeling the axes of graphs the use of % and ppm in the denominator is to be avoided. Although one would write  $x(^{13}\text{C}) = 1.1\%$ , the notation  $100\ x$  is to be preferred to  $x/\%$  in tables and graphs.

The further symbols listed in the table below are also to be found in the literature, but their use is to be deprecated. Note that the names and symbols for  $10^{-9}$  and  $10^{-12}$  in this table are based on the American system of names. In other parts of the world a billion sometimes stands for  $10^{12}$  and a trillion for  $10^{18}$ . Note also that the symbol ppt is sometimes used for part per thousand, and sometimes for part per trillion.

To avoid ambiguity the symbols ppb, ppt and pphm should not be used.

<i>Name</i>	<i>Symbol</i>	<i>Value</i>	<i>Examples</i>
Part per hundred	pph	$10^{-2}$	(Exactly equivalent to percent, %)
Part per thousand Per mille <sup>a</sup>	ppt ‰	$10^{-3}$	Atmospheric carbon dioxide is depleted in carbon-13 mass fraction by 7‰ (or 7 ppt) relative to ocean water
		$10^{-3}$	
Part per hundred million	pphm	$10^{-8}$	The mass fraction of impurity in the metal was less than 5 pphm
Part per billion	ppb	$10^{-9}$	The air quality standard for ozone is a volume fraction of $\phi = 120$ ppb
Part per trillion	ppt	$10^{-12}$	The natural background volume fraction of NO in air was found to be $\phi = 140$ ppt
Part per quadrillion	ppq	$10^{-15}$	

<sup>a</sup>The permille is also spelled per mille, per mill, permil, or pro mille.

# APPENDIX 5. PROPERTIES OF PARTICLES, ELEMENTS AND NUCLIDES

## Properties of Some Particles

Name	Symbol <sup>a</sup>	Spin <i>I</i>	Charge number <i>z</i>	Rest mass		Magnetic moment $\mu$ ( $\mu_N$ )	Mean life $\tau$ (s)
				<i>m</i> (u)	$mc^2$ (MeV)		
Photon	$\gamma$	1	0	0	0		
Neutrino	$\nu_e$	1/2	0	0	0		
Electron <sup>b</sup>	e	1/2	−1	$5.485\,799\,03\,(13) \times 10^{-4}$	$0.510\,999\,06\,(15)$	$1.001\,159\,652\,193\,(10)^c$	
Muon	$\mu^\pm$	1/2	$\pm 1$	$0.113\,428\,913\,(17)$	$105.658\,389\,(34)$	$1.001\,165\,923\,(8)^d$	$2.1973\,(4) \times 10^{-6}$
Pion	$\pi^\pm$	1	$\pm 1$	$0.149\,832\,3\,(8)$	$139.5679\,(7)$		$2.6030\,(24) \times 10^{-8}$
Pion	$\pi^0$	1	0	$0.144\,900\,8\,(9)$	$134.9743\,(8)$		$8.4\,(6) \times 10^{-17}$
Proton	p	1/2	1	$1.007\,276\,470\,(12)$	$938.272\,31\,(28)$	$2.792\,847\,386\,(63)$	
Neutron	n	1/2	0	$1.008\,664\,904\,(14)$	$939.565\,63\,(28)$	$-1.913\,042\,75\,(45)$	$889.1\,(21)$
Deuteron	d	1	1	$2.013\,553\,214\,(24)$	$1875.613\,39\,(53)$	$0.857\,437\,6\,(1)$	
Triton	t	1/2	1	$3.015\,500\,71\,(4)$	$2808.921\,78\,(85)$	$2.978\,960\,(1)$	
Helion	h	1/2	2	$3.014\,932\,23\,(4)$	$2808.392\,25\,(85)$	$-2.127\,624\,(1)$	
$\alpha$ -Particle	$\alpha$	0	2	$4.001\,506\,170\,(50)$	$3727.380\,3\,(11)$	0	

<sup>a</sup>The Particle Data Group recommends the use of italic symbols for particles and this has been adopted by many physicists.

<sup>b</sup>The electron as  $\beta$ -particle is sometimes denoted by  $\beta$ .

<sup>c</sup>The value is given in Bohr magnetons  $\mu/\mu_B$ ,  $\mu_B = eh/2m_e$ .

<sup>d</sup>The value is given as  $\mu/\mu_\mu$ , where  $\mu_\mu = eh/2m_\mu$ .

In nuclear physics and chemistry the masses of particles are often quoted as their energy equivalents (usually in megaelectronvolts). The unified atomic mass unit corresponds to  $931.494\,32\,(28)$  MeV.

Atom-like pairs of a positive particle and an electron are sometimes sufficiently stable to be treated as individual entities with special names.

### Examples

Positronium ( $e^+ e^-$ )  $m(e^+ e^-) = 1.097\,152\,503\,(26) \times 10^{-3}$  u

Muonium ( $\mu^+ e^-$ ; Mu)  $m(\text{Mu}) = 0.113\,977\,478\,(17)$  u

The positive or negative sign for the magnetic moment of a particle implies that the orientation of the magnetic dipole with respect to the angular momentum corresponds to the rotation of a positive or negative charge, respectively.

## Atomic Weights of the Elements 2001

Values from the 2001 table *Pure Appl. Chem.*, 2003, 75: 1107–1122. The values of zinc, krypton, molybdenum, and dysprosium have been modified. The approved name for element 110 is included; see *Pure Appl. Chem.*, 2003, 75: 1613–1615. The proposed name for element 111 is also included. Reproduced from <http://www.chem.qmul.ac.uk/iupac/AtWt/>. The table is also available from mirror sites in Germany, Japan, South Africa, and USA. World Wide Web version of atomic weight data prepared by G. P. Moss, originally from a file provided by D. R. Lide. Note: The claim (*Phys. Rev. Lett.*, 1999, 83: 1104) for elements 116 and 118 has been withdrawn (see *Chem. Eng. News*, 2001, 79: 10 (6 August 2001); 2002, 80: 12 (22 July 2002); *Phys. Rev. Lett.*, 2002, 89: 039901). Previous values may be consulted from the 1993 table, the 1995 table, the 1997 table or the 1999 table. The original paper should be consulted for details of the half-life of the radioisotopes quoted below. Also there is a report on the different isotopic compositions of some non-terrestrial materials. A number in parentheses indicates the uncertainty in the last digit of the atomic weight.

## List of Elements in Name Order

Atomic no.	Symbol	Name	Atomic wt.	Notes
89	Ac	Actinium	[227]	5
13	Al	Aluminum	26.981 538 (2)	
95	Am	Americium	[243]	5
51	Sb	Antimony	121.760 (1)	1
18	Ar	Argon	39.948 (1)	1, 2
33	As	Arsenic	74.921 60 (2)

40	Zr	Zirconium	91.224 (2)	1

1. Geological specimens are known in which the element has an isotopic composition outside the limits for normal material. The difference between the atomic weight of the element in such specimens and that given in the Table may exceed the stated uncertainty.
2. The range in isotopic composition of normal terrestrial material prevents a more precise value being given; the tabulated value should be applicable to any normal material.
3. Modified isotopic compositions may be found in commercially available material because it has been subject to an undisclosed or inadvertent isotopic fractionation. Substantial deviations in atomic weight of the element from that given in the Table can occur.
4. Commercially available Li materials have atomic weights that range between 6.939 and 6.996; if a more accurate value is required, it must be determined for the specific material [range quoted for 1995 table 6.94 and 6.99].
5. Element has no stable nuclides. The value enclosed in brackets, e.g., [209], indicates the mass number of the longest-lived isotope of the element. However three such elements (Th, Pa, and U) do have a characteristic terrestrial isotopic composition, and for these an atomic weight is tabulated.
6. The names and symbols for elements 112–118 are under review. The temporary system recommended by J Chatt (1979) *Pure Appl. Chem.*, 51: 381–384 is used above. The names of elements 101–109 were agreed in 1997 (see *Pure Appl. Chem.*, 1997, 69: 2471–2473) and for element 110 in 2003 (see *Pure Appl. Chem.*, 2003, 75: 1613–1615). The proposed name for element 111 is also included.

## Properties of Nuclides

The table contains the following properties of naturally occurring and some unstable nuclides:

Column

1.  $Z$  is the atomic number (number of protons) of the nuclide.
2. Symbol of the element.
3.  $A$  is the mass number of the nuclide. The “\*” sign denotes an unstable nuclide (for elements without naturally occurring isotopes it is the most stable nuclide) and the “#” sign a nuclide of sufficiently long lifetime to enable the determination of its isotopic abundance.
4. The atomic mass is given in unified atomic mass units,  $u = m_a(^{12}\text{C})/12$ , together with the standard errors in parentheses and applicable to the last digits quoted.
5. Isotopic abundances are given as mole fractions,  $x$ , of the corresponding atoms in percents. They were recommended in 1989 by the IUPAC Commission on Atomic Weights and Isotopic Abundances. The uncertainties given in parentheses are applicable to the last digits quoted and cover the range of probable variations in the materials as well as experimental errors.
6.  $I$  is the nuclear spin quantum number.
7. Under magnetic moment the maximum  $z$ -component expectation value of the magnetic dipole moment,  $m$ , in nuclear magnetons is given. The positive or negative sign implies that the orientation of the magnetic dipole with respect to the angular momentum corresponds to the rotation of a positive or negative charge, respectively. An asterisk indicates that more than one value is given in the original compilation. The value of highest precision or most recent date is given here.
8. Under quadrupole moment, the electric quadrupole moment area is given in units of square femtometres,  $\text{fm}^2 = 10^{-30} \text{m}^2$ , although most of the tables quote them in barns ( $1 \text{ barn} = 10^{-28} \text{m}^2 = 100 \text{ fm}^2$ ). The positive sign implies a prolate nucleus, the negative sign an oblate nucleus. The data for  $Z \leq 20$  were taken from the compilation by P. Pyykkö with values for Cl and Ca corrected by D. Sundholm (private communication), and the others from P. Raghavan. An asterisk indicates that more than one value is given in the original compilation.

# APPENDIX 4. FUNDAMENTAL PHYSICAL CONSTANTS

The following values were recommended by the CODATA Task Group on Fundamental Constants in 1986. For each constant the standard deviation uncertainty in the least significant digits is given in parentheses.

## Fundamental constants

Quantity	Symbol	2002 Value (standard uncertainty) <sup>a</sup>	Unit
Speed of light in vacuum	$c_0$	299 792 458	$\text{m s}^{-1}$
Magnetic constant	$\mu_0$	$4\pi \times 10^{-7}$	$\text{H m}^{-1}$
Electric constant	$\epsilon_0 = 1/\mu_0 c_0^2$	8.854 187 817 ...	$\times 10^{-12} \text{ F m}^{-1}$
Planck constant	$h$	6.626 069 3 (11)	$\times 10^{-34} \text{ J s}$
Elementary charge (charge on a proton)	$e$	1.602 176 53 (14)	$\times 10^{-19} \text{ C}$
Electron rest mass	$m_e$	9.109 382 6 (16)	$\times 10^{-31} \text{ kg}$
Proton rest mass	$m_p$	1.672 621 71 (29)	$\times 10^{-27} \text{ kg}$
Atomic mass constant (dalton, or unified atomic mass unit, $m(^{12}\text{C})/12$ )	$m_u$ $= \text{Da} = \text{u}$	1.660 538 86 (28)	$\times 10^{-27} \text{ kg}$
Avogadro constant	$L, N_A$	6.022 141 5 (10)	$\times 10^{23} \text{ mol}^{-1}$
Boltzmann constant	$k, k_B$	1.380 650 5 (24)	$\times 10^{-23} \text{ J K}^{-1}$
Faraday constant	$F$	96 485.33 83 (83)	$\text{C mol}^{-1}$
Gas constant	$R$	8.314 472 (15)	$\text{J mol}^{-1} \text{ K}^{-1}$
Fine structure constant	$\alpha$	7.297 352 568 (24)	$\times 10^{-3}$
Bohr radius	$a_0$	0.529 177 210 8 (18)	$\times 10^{-10} \text{ m}$
Hartree energy	$E_h$	4.359 744 17 (75)	$\times 10^{-18} \text{ J}$
Rydberg constant	$R_\infty$	10 973 731.568 525 (73)	$\text{m}^{-1}$
Bohr magneton	$\mu_B$	9.274 009 49 (80)	$\times 10^{-24} \text{ J T}^{-1}$
Landé $g$ factor for free electron	$g$	2.002 319 304 371 8 (75)	
Nuclear magneton	$\mu_N$	5.050 783 43 (43)	$\times 10^{-27} \text{ J T}^{-1}$
Relative atomic mass of the electron	$A_r(e)$	5.485 799 094 5 (24)	$\times 10^{-4}$
Newtonian constant of gravitation	$G$	6.674 2 (10)	$\times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$

<sup>a</sup>The standard uncertainty given in parenthesis (i.e., the estimated standard deviation of the value quoted), applies to the least significant digits of each constant.

## Values of Common Mathematical Constants

Mathematical constant	Symbol	Value
Ratio of circumference to diameter of a circle	$\pi$	3.141 592 653 59
Base of natural logarithms	$e$	2.718 281 828 46
Natural logarithm of 10	$\ln 10$	2.302 585 092 99

# APPENDIX 6. CONVERSION OF UNITS

© 1993, Blackwell Science. Published by Elsevier Ltd. All rights reserved.

“Appendix 6. Conversion of Units” reproduced with permission from Mills I *et al.* (1993) *Quantities, Units and Symbols in Physical Chemistry*, 2nd edn., Oxford: Blackwell Science.

The table below gives conversion factors from a variety of units to the corresponding SI unit. Examples of the use of this table have already been given in the preceding section. For each physical quantity the name is given, followed by the recommended symbol(s). Then the SI unit is given, followed by the esu, emu, Gaussian unit (Gau), atomic unit (au), and other units in common use, with their conversion factors to SI. The constant  $\zeta$  which occurs in some of the electromagnetic conversion factors is the (exact) pure number  $2.997\,924\,58 \times 10^{10} = c_0/(\text{cm s}^{-1})$ .

The inclusion of non-SI units in this table should not be taken to imply that their use is to be encouraged. With some exceptions, SI units are always to be preferred to non-SI units. However, since many of the units below are to be found in the scientific literature, it is convenient to tabulate their relation to the SI.

For convenience units in the esu and Gaussian systems are quoted in terms of the four dimensions *length*, *mass*, *time*, and *electric charge*, by including the franklin (Fr) as an abbreviation for the electrostatic unit of charge and  $4\pi\epsilon_0$  as a constant with dimensions  $(\text{charge})^2/(\text{energy} \times \text{length})$ . This gives each physical quantity the same dimensions in all systems, so that all conversion factors are pure numbers. The factors  $4\pi\epsilon_0$  and the Fr may be eliminated by writing  $\text{Fr} = \text{esu of charge} = \text{erg}^{1/2} \text{cm}^{1/2} = \text{cm}^{3/2} \text{g}^{1/2} \text{s}^{-1}$ , and  $4\pi\epsilon_0 = \epsilon_0^{(\text{ir})} = 1 \text{ Fr}^2 \text{erg}^{-1} \text{cm}^{-1} = 1$ , to recover esu expressions in terms of three base units. The symbol Fr should be regarded as a compact representation of ‘esu of charge’.

Conversion factors are either given exactly (when the = sign is used), or they are given to the approximation that the corresponding physical constants are known (when the  $\approx$  sign is used). In the latter case the uncertainty is always less than  $\pm 5$  in the last digit quoted.

Name	Symbol	Relation to SI
<i>Length, l</i>		
Meter (SI unit)	m	
Centimeter (cgs unit)	cm	$= 10^{-2} \text{ m}$
Bohr (au)	$a_0, b$	$= 4\pi\epsilon_0 \hbar^2 / m_e e^2 \approx 5.291\,77 \times 10^{-11} \text{ m}$
Ångström	Å	$= 10^{-10} \text{ m}$
Micron	$\mu$	$= \mu\text{m} = 10^{-6} \text{ m}$
x unit	X	$\approx 1.002 \times 10^{-13} \text{ m}$

<i>Magnetic susceptibility, <math>\chi</math>, <math>\kappa</math></i>		
SI unit	1	
emu, Gau	1	
(But note: in practice susceptibilities quoted in the context of emu or Gaussian units are always values for $\chi^{(\text{ir})} = \chi/4\pi$ ; thus when $\chi^{(\text{ir})} = 10^{-6}$ , $\chi = 4\pi \times 10^{-6}$ .)		
<i>Molar magnetic susceptibility, <math>\chi_{\text{m}}</math></i>		
SI unit	$\text{m}^3 \text{mol}^{-1}$	
emu, Gau	$\text{cm}^3 \text{mol}^{-1}$	$= 10^{-6} \text{m}^3 \text{mol}^{-1}$
(But note: in practice the units $\text{cm}^3 \text{mol}^{-1}$ usually imply that the irrational molar susceptibility is being quoted, $\chi_{\text{m}}^{(\text{ir})} = \chi_{\text{m}}/4\pi$ ; thus, for example, if $\chi_{\text{m}}^{(\text{ir})} = -15 \times 10^{-6} \text{cm}^3 \text{mol}^{-1}$ , which is often written as ‘ $-15 \text{cgs ppm}$ ’, then $\chi_{\text{m}} = -1.88 \times 10^{-10} \text{m}^3 \text{mol}^{-1}$ .)		

<sup>a</sup>Note that the day is not exactly defined in terms of the second since so-called leap-seconds are added or subtracted from the day semiannually in order to keep the annual average occurrence of midnight at 24:00 on the clock.

<sup>b</sup>The year is not commensurable with the date and not a constant. Prior to 1967, when the atomic standard was introduced, the tropical year 1900 served as the basis for the definition of the second. For the epoch 1900.0, it amounted to  $365.242\,198\,79 \text{d} \approx 31\,556\,925.975 \text{s}$  and it decreases by 0.530 seconds per century. The calendar years are exactly defined in terms of the day:

$$\text{Julian year} = 365.25 \text{ d}$$

$$\text{Gregorian year} = 365.2425 \text{ d}$$

The definition in the table corresponds to the Gregorian year. This is an average based on a year of length 365 days, with leap years of 366 days; leap years are taken *either* when the year is divisible by 4 but is not divisible by 100, *or* when the year is divisible by 400.

<sup>c</sup>1 N is approximately the force exerted by the earth upon an apple.

<sup>d</sup> $T/^{\circ}\text{R} = (9/5) T/\text{K}$ . Also, Celsius temperature  $\theta$  is related to thermodynamic temperature  $T$  by the equation

$$\theta/^{\circ}\text{C} = T/\text{K} - 273.15$$

Similarly Fahrenheit temperature  $\theta_{\text{F}}$  is related to Celsius temperature  $\theta$  by the equation

$$\theta_{\text{F}}/^{\circ}\text{F} = (9/5)(\theta/^{\circ}\text{C}) + 32$$

<sup>e</sup>The name ‘amagat’ is unfortunately used as a unit for both molar volume and amount density. Its value is slightly different for different gases, reflecting the deviation from ideal behavior for the gas being considered.

<sup>f</sup>The unit röntgen, employed to express exposure to X- or  $\gamma$ -radiations, is equal to:  $\text{R} = 2.58 \times 10^{-4} \text{C kg}^{-1}$ .

<sup>g</sup>The units in quotation marks for electric potential through polarizability may be found in the literature, although they are strictly incorrect; they should be replaced in each case by the units given in the symbol column. Thus, for example, when a quadrupole moment is quoted in ‘ $\text{cm}^2$ ’, the correct unit is  $e \text{cm}^2$ ; and when a polarizability is quoted in ‘ $\text{\AA}^3$ ’, the correct unit is  $4\pi\epsilon_0 \text{\AA}^3$ .

<sup>h</sup>The Bohr magneton  $\mu_{\text{B}}$  is sometimes denoted BM (or B.M.), but this is not recommended.

## APPENDIX 7. STATISTICAL TABLES

The following tables are presented in a format that is compatible with the needs of analytical chemists: the significance level  $P=0.05$  has been used in most cases, and it has been assumed that the number of measurements available is fairly small. Except where stated otherwise, these abbreviated tables have been reproduced from *Elementary Statistics Tables* by Henry R. Neave, published by George Allen & Unwin Ltd. (Tables 1–3 and 6–12). The reader requiring statistical data corresponding to significance levels and/or numbers of measurements not covered in the tables is referred to these sources.

**Table 1** The  $t$ -distribution

Value of $t$ for a confidence interval of:	90%	95%	98%	99%
Critical value of $ t $ for $P$ values of:	0.10	0.05	0.02	0.01
Number of degrees of freedom				
1	6.31	12.71	31.82	63.66
2	2.92	4.30	6.96	9.92
3	2.35	3.18	4.54	5.84
4	2.13	2.78	3.75	4.60
5	2.02	2.57	3.36	4.03
6	1.94	2.45	3.14	3.71
7	1.89	2.36	3.00	3.50
8	1.86	2.31	2.90	3.36
9	1.83	2.26	2.82	3.25
10	1.81	2.23	2.76	3.17
12	1.78	2.18	2.68	3.05
14	1.76	2.14	2.62	2.98
16	1.75	2.12	2.58	2.92
18	1.73	2.10	2.55	2.88
20	1.72	2.09	2.53	2.85
30	1.70	2.04	2.46	2.75
50	1.68	2.01	2.40	2.68
$\infty$	1.64	1.96	2.33	2.58

The critical values of  $|t|$  are appropriate for a *two-tailed* test. For a *one-tailed* test the value is taken from the column for *twice* the desired  $P$ -value, e.g., for a *one-tailed* test,  $P=0.05$ , 5 degrees of freedom, the critical value is read from the  $P=0.10$  column and is equal to 2.02.

**Table 2** Critical values of  $F$  for a *one-tailed* test ( $P=0.05$ )

$\nu_1 \backslash \nu_2$	1	2	3	4	5	6	7	8	9	10	12	15	20
1	161.4	199.5	215.7	224.6	230.2	234.0	236.8	238.9	240.5	241.9	243.9	245.9	248.0
2	18.51	19.00	19.16	19.25	19.30	19.33	19.35	19.37	19.38	19.40	19.41	19.43	19.45
3	10.13	9.552	9.277	9.117	9.013	8.941	8.887	8.845	8.812	8.786	8.745	8.703	8.660
4	7.709	6.944	6.591	6.388	6.256	6.163	6.094	6.041	5.999	5.964	5.912	5.858	5.803
5	6.608	5.786	5.409	5.192	5.050	4.950	4.876	4.818	4.772	4.735	4.678	4.619	4.558

$\nu_1$  = number of degrees of freedom of the numerator and  $\nu_2$  = number of degrees of freedom of the denominator.

**Table 4** Critical values of  $Q$  ( $P=0.05$ ) for a two-sided Dixon's test for outliers

Sample size	Critical value
4	0.831
5	0.717
6	0.621
7	0.570

Reproduced from King EP, Journal American Statistical Association.

**Table 5** Critical values of  $G$  ( $P=0.05$ ) for a two-sided Grubbs' test for outliers

Sample size	Critical value
3	1.155
4	1.481
5	1.715
6	1.887
7	2.020
8	2.126
9	2.215
10	2.290

Reproduced from Barnett V and Lewis T (1984) *Outliers in Statistical Data*, 2nd edn. John Wiley & Sons Ltd.

**Table 6** Critical values of  $\chi^2$  ( $P=0.05$ )

Number of degrees of freedom	Critical value
1	3.84
2	5.99
3	7.81
4	9.49
5	11.07
6	12.59
7	14.07
8	15.51
9	16.92
10	18.31

**Table 7** The sign test

$n$	$r=0$	1	2	3	4	5	6	7
4	0.063	0.313	0.688					
5	0.031	0.188	0.500					
6	0.016	0.109	0.344	0.656				
7	0.008	0.063	0.227	0.500				
8	0.004	0.035	0.144	0.363	0.637			
9	0.002	0.020	0.090	0.254	0.500			
10	0.001	0.011	0.055	0.172	0.377	0.623		
11	0.001	0.006	0.033	0.113	0.274	0.500		
12	0.000	0.003	0.019	0.073	0.194	0.387	0.613	
13	0.000	0.002	0.011	0.046	0.133	0.290	0.500	
14	0.000	0.001	0.006	0.029	0.090	0.212	0.395	0.605
15	0.000	0.000	0.004	0.018	0.059	0.151	0.304	0.500

The table uses the binomial distribution with  $P=0.5$  to give the probabilities of  $r$  or less successes for  $n=4-15$ . These values correspond to a *one*-tailed sign test and should be doubled for a *two*-tailed test.

**Table 8** Wilcoxon signed rank test. Critical values for the test statistic at  $P=0.05$ 

$n$	One-tailed test	Two-tailed test
5	0	NA
6	2	0
7	3	2
8	5	3
9	8	5
10	10	8
11	13	10
12	17	13
13	21	17
14	25	21
15	30	25

The null hypothesis can be rejected when the test statistic is  $\leq$  the tabulated value. NA indicates that the test cannot be applied.

**Table 9** Mann-Whitney  $U$ -test. Critical values for  $U$  or the lower of  $T_1$  and  $T_2$  at  $P=0.05$ 

$n_1$	$n_2$	One-tailed test	Two-tailed test
3	3	0	NA
3	4	0	NA
3	5	1	0
3	6	2	1
4	4	1	0
4	5	2	1
4	6	3	2
4	7	4	3
5	5	4	2
5	6	5	3
5	7	6	5
6	6	7	5
6	7	8	6
7	7	11	8

The null hypothesis can be rejected when  $U$  or the lower  $T$  value is  $\leq$  the tabulated value. NA indicates that the test cannot be applied.

**Table 10** The Spearman rank correlation coefficient. Critical values for  $\rho$  at  $P=0.05$ 

$n$	One-tailed test	Two-tailed test
5	0.900	1.000
6	0.829	0.886
7	0.714	0.786
8	0.643	0.738
9	0.600	0.700
10	0.564	0.649
11	0.536	0.618
12	0.504	0.587
13	0.483	0.560
14	0.464	0.538
15	0.446	0.521
16	0.429	0.503
17	0.414	0.488
18	0.401	0.472
19	0.391	0.460
20	0.380	0.447

**Table 11** The Kolmogorov goodness-of-fit test

<i>n</i>	<i>One-tailed test</i>	<i>Two-tailed test</i>
1	0.950	0.975
2	0.776	0.842
3	0.636	0.708
4	0.565	0.624
5	0.509	0.563
6	0.468	0.519
7	0.436	0.483
8	0.410	0.454
9	0.388	0.430
10	0.369	0.409
11	0.352	0.392
12	0.338	0.375
13	0.326	0.361
14	0.314	0.349
15	0.304	0.338
16	0.295	0.327
17	0.286	0.318
18	0.278	0.309
19	0.271	0.301
20	0.265	0.294

Critical values for *one*-tailed and *two*-tailed tests at  $P = 0.05$ . The appropriate value is compared with the maximum difference between the experimental and theoretical cumulative frequency curves.

**Table 12** The Kolmogorov test for normality

<i>n</i>	<i>One-tailed test</i>	<i>Two-tailed test</i>
3	0.367	0.376
4	0.345	0.375
5	0.319	0.343
6	0.297	0.323

9	0.252	0.274
10	0.241	0.262
11	0.231	0.251
12	0.222	0.242
13	0.215	0.234
14	0.208	0.226
15	0.201	0.219
16	0.195	0.213
17	0.190	0.207
18	0.185	0.202
19	0.181	0.197
20	0.176	0.192

Critical values for *one*-tailed and *two*-tailed tests at  $P = 0.05$ . The appropriate value is compared with the maximum difference between the experimental and theoretical cumulative frequency curves.

# APPENDIX 8. BIOLOGICAL BUFFERS

**Table 1** This table of frequently used buffers gives the  $pK_a$  value at 25°C and the useful pH range of each buffer. The buffers are listed in order of increasing pH

Acronym	Name	Mol. wt.	$pK_a$	Useful pH range
MES	2-( <i>N</i> -morpholino)ethanesulfonic acid	195.2	6.1	5.5–6.7
BIS TRIS	<i>Bis</i> (2-hydroxyethyl)iminotris(hydroxymethyl)methane	209.2	6.5	5.8–7.2
ADA	<i>N</i> -(2-acetamido)-2-iminodiacetic acid	190.2	6.6	6.0–7.2
ACES	2-[(2-Amino-2-oxoethyl)amino]ethanesulfonic acid	182.2	6.8	6.1–7.5
PIPES	Piperazine- <i>N,N'</i> - <i>bis</i> (2-ethanesulfonic acid)	302.4	6.8	6.1–7.5
MOPSO	3-( <i>N</i> -morpholino)-2-hydroxypropanesulfonic acid	225.3	6.9	6.2–7.6
BIS TRIS PROPANE	1,3- <i>Bis</i> [ <i>tris</i> (hydroxymethyl)methylamino]propane	282.3	6.8 <sup>a</sup>	6.3–9.5
BES	<i>N,N</i> - <i>bis</i> (2-hydroxyethyl)-2-aminoethanesulfonic acid	213.2	7.1	6.4–7.8
MOPS	3-( <i>N</i> -morpholino)propanesulfonic acid	209.3	7.2	6.5–7.9
HEPES	<i>N</i> -(2-hydroxyethyl)piperazine- <i>N'</i> -(2-ethanesulfonic acid)	238.3	7.5	6.8–8.2
TES	<i>N</i> - <i>tris</i> (hydroxymethyl)methyl-2-aminoethanesulfonic acid	229.2	7.5	6.8–8.2
DIPSO	3-[ <i>N,N</i> - <i>bis</i> (2-hydroxyethyl)amino]-2-hydroxypropanesulfonic acid	243.3	7.6	7.0–8.2
TAPSO	3-[ <i>N</i> - <i>tris</i> (hydroxymethyl)methylamino]-2-hydroxypropanesulfonic acid	259.3	7.6	7.0–8.2
TRIZMA	Tris(hydroxymethyl)aminomethane

# APPENDIX 10. STANDARD POTENTIALS IN AQUEOUS SOLUTIONS

© 1985 Marcel Dekker. Published by Elsevier Ltd. All rights reserved.

Selected half-reaction potentials are listed in order of increasingly positive (anodic) assignments, providing a convenient guide to redox couples in a given range of standard potentials. The synopsis consists of two tables, one each for acid and basic solutions, which have been advisedly restricted to selected half-reactions.

# APPENDIX 12. IMPORTANT PEAKS IN THE MASS SPECTRA OF COMMON SOLVENTS

© 1989, CRC Press. Published by Elsevier Ltd. All rights reserved.

“Appendix 12. Important Peaks in Mass Spectra of Common Solvents” is reproduced with permission from Lide DR (editor in chief) (1993) *CRC Handbook of Chemistry and Physics*, 72nd edn., Boca Raton: CRC Press.

The following table gives the most important peaks that appear in the mass spectra of the most common solvents which might occur as an impurity in organic samples. The solvents are classified in ascending order of their  $M^+$  peaks. The highest intensity peaks are indicated with (100%).

Important peaks in the mass spectra of common solvents

<i>Solvents</i>	<i>Formula</i>	<i>M<sup>+</sup></i>	<i>Important peaks (m/z)</i>
Water	H <sub>2</sub> O	18 (100%)	17
Methanol	CH <sub>3</sub> OH	32	31 (100%), 29, 15
Acetonitrile	CH <sub>3</sub> CN	41 (100%)	40, 39, 38, 28, 15
Ethanol	CH <sub>3</sub> CH <sub>2</sub> OH	46	45, 31 (100%), 27, 15
Dimethyl ether	CH <sub>3</sub> OCH <sub>3</sub>	46 (100%)	45, 29, 15
Acetone	CH <sub>3</sub> COCH <sub>3</sub>	58	43 (100%), 42, 39, 27, 15
Acetic acid	CH <sub>3</sub> CO <sub>2</sub> H	60	45, 43, 18, 15
Ethylene glycol	HOCH <sub>2</sub> CH <sub>2</sub> OH	62	43, 33, 31 (100%), 29, 18, 15
Furan	C <sub>4</sub> H <sub>4</sub> O	68 (100%)	42, 39, 38, 37, 29, 18
Tetrahydrofuran	C <sub>4</sub> H <sub>8</sub> O	72	71, 43, 42 (100%), 41, 40, 39, 27, 18, 15
n-Pentane	C <sub>5</sub> H <sub>12</sub>	72	57, 43 (100%), 42, 41, 39, 29, 28, 27, 15
Dimethylformamide (DMF)	HCON(CH <sub>3</sub> ) <sub>2</sub>	73 (100%)	58, 44, 42, 30, 29, 28, 18, 15
Diethylether	(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub> O	74	59, 45, 41, 31 (100%), 29, 27, 15
Methylacetate	CH <sub>3</sub> CO <sub>2</sub> CH <sub>3</sub>	74	59, 43 (100%), 42, 32, 29, 28, 15
Carbon disulphide	CS <sub>2</sub>	76 (100%)	64, 44, 38, 32
Benzene	C <sub>6</sub> H <sub>6</sub>	78 (100%)	77, 52, 51, 50, 39, 28
Pyridine	C <sub>5</sub> H <sub>5</sub> N	79 (100%)	80, 78, 53, 52, 51, 50, 39, 26
Dichloromethane	CH <sub>2</sub> Cl <sub>2</sub>	84	86, 51, 49 (100%), 48, 47, 35, 28
Cyclohexane	C <sub>6</sub> H <sub>12</sub>	84	69, 56, 55, 43, 42, 41, 39, 27
n-Hexane	C <sub>6</sub> H <sub>14</sub>	86	85, 71, 69, 57 (100%), 43, 42, 41, 39, 29, 28, 27
p-Dioxane	C <sub>4</sub> H <sub>8</sub> O <sub>2</sub>	88 (100%)	87, 58, 57, 45, 43, 31, 30, 29, 28
Tetramethylsilane (TMS)	(CH <sub>3</sub> ) <sub>4</sub> Si	88	74, 73, 55, 45, 43, 29
1,2-Dimethoxy ethane	(CH <sub>3</sub> OCH <sub>2</sub> ) <sub>2</sub>	90	60, 58, 45 (100%), 31, 29
Toluene	C <sub>6</sub> H <sub>5</sub> CH <sub>3</sub>	92	91 (100%), 65, 51, 39, 28
Chloroform	CHCl <sub>3</sub>	118	120, 83, 81 (100%), 47, 35, 28
Chloroform-d <sub>1</sub>	CDCl <sub>3</sub>	119	121, 84, 82 (100%), 48, 47, 35, 28
Carbon tetrachloride	CCl <sub>4</sub>	152 (not seen)	121, 119, 117 (100%), 84, 82, 58.5, 47, 35, 28
Tetrachloroethene	CCl <sub>2</sub> = CCl <sub>2</sub>	164 (not seen)	168, 166 (100%), 165, 164, 131, 128, 129, 95, 94, 82, 69, 59, 47, 31, 24
